NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Pharmacotherapy

A Pathophysiologic Approach

Eighth Edition

Joseph T. DiPiro, PharmD, FCCP
Executive Dean and Professor, South Carolina College of Pharmacy, University of South Carolina, Columbia South Carolina and Medical University of South Carolina, Charleston, South Carolina

Robert L. Talbert, PharmD, FCCP, BCPS, CLS
Professor, College of Pharmacy, University of Texas at Austin, Pharmacotherapy Division, Professor, School of Medicine, University of Texas Health Science Center at San Antonio, Pharmacotherapy Education & Research Center (PERC), UTHSCSA-PERC, San Antonio, Texas

Gary C. Yee, PharmD, FCCP, BCOP
Professor and Associate Dean for Academic Affairs, College of Pharmacy, University of Nebraska Medical Center, Omaha, Nebraska

Gary R. Matzke, PharmD, FCP, FCCP, FASN
Professor and Associate Dean for Clinical Research and Public Policy, School of Pharmacy, Professor of Internal Medicine, Nephrology Division, School of Medicine, Virginia Commonwealth University, Richmond, Virginia

Barbara G. Wells, PharmD, FCCP, BCPP
Dean and Professor, Executive Director of the Research Institute of Pharmaceutical Sciences, School of Pharmacy, The University of Mississippi, Oxford, Mississippi

L. Michael Posey, BSPharm
Editorial Director, Periodicals Department, American Pharmacists Association, Washington D.C.

Summary: “The most comprehensive, widely used, and evidence-based pharmacotherapy text available. Hailed by Doody’s Review Service as “one of the best in pharmacy” Pharmacotherapy: A Pathophysiologic Approach is unmatched in its ability to help students develop a mastery of evidence-based medicine for optimum patient outcomes. The eighth edition will feature the addition of SI units throughout and an increased number of global examples and clinical questions. Features unparalleled guidance in the development of pharmaceutical care plans. Fullcolor presentation. Key Concepts in each chapter. Critical Presentation boxes summarize common disease signs and symptoms. Clinical Controversy boxes examine complicated issues you face when providing drug therapy. NEW material added to the online learning center. EXPANDED evidence-based recommendations. EXPANDED coverage of timely issues such as palliative care and pain medicine. Therapeutic recommendations in each disease-specific chapter”—Provided by publisher.

Please tell the authors and publisher what you think of this book by sending your comments to pharmacotherapy@mcgraw-hill.com. Please put the author and title of the book in the subject line.

TERMS OF USE

Neither McGraw-Hill nor its licensors shall be liable to you or anyone else for any inaccuracy, error or omission, regardless of cause, in the work or for any damages resulting therefrom. McGraw-Hill has no responsibility for the content of any information accessed through the work. Under no circumstances shall McGraw-Hill and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

DEDICATION

To our patients, who have challenged and inspired us
and given meaning to all our endeavors.

To practitioners who continue to improve patient health outcomes
and thereby serve as role models for their colleagues and students
while clinging tenaciously to the highest standards of practice.

To our mentors, whose vision provided educational and training
programs that encouraged our professional growth and challenged us
to be innovators in our patient care, research, and education.

To our faculty colleagues for their efforts and support for our mission
to provide a comprehensive and challenging educational
foundation for the pharmacists of the future.

And finally to our families for the time that they have sacrificed
so that this eighth edition would become a reality.

Foreword xxvii

Foreword to the First Edition xxix

Preface xxxi

SECTION 1
Foundation Issues

Section Editor: L. Michael Posey

1. Pharmacoeconomics: Principles, Methods, and Applications 1
   Lisa Sanchez Trask
2. Health Outcomes and Health-Related Quality of Life 3
   Stephen Joel Coons
3. Health Literacy and Medication Use 5
   Oralia V. Bazaldua and Sunil Kripalani
4. Cultural Competency 7
   Jeri J. Sias, Amanda M. Loya, José O. Rivera, Arthur A. Islas, and Ulysses J. Urquidi
5. Principles and Practices of Medication Safety 9
   Scott M. Mark, Jeffrey D. Little, Sarah E. Adkins, and Robert J. Weber
6. Evidence-Based Medicine 11
   Elaine Chiquette and L. Michael Posey
7. Documentation of Pharmacy Services 13
   George E. MacKinnon III and Neil J. MacKinnon
8. Clinical Pharmacokinetics and Pharmacodynamics 15
   Larry A. Bauer
9. Pharmacogenetics 17
   Larisa H. Cavallari and Y. W. Francis Lam
10. Pediatrics 19
    Milap C. Nahata and Carol Taketomo
11. Geriatrics 21
    Emily R. Hajjar, Shelly L. Gray, David R.P. Guay, Catherine I. Starner, Steven M. Handler, and Joseph T. Hanlon
12. Palliative Care 23
    Jill Astolfi
13. Pharmacoepidemiology 25
    Andy Stergachis, Thomas K. Hazlet, and Denise Boudreau
14. Clinical Toxicology 27
    Peter A. Chyka
15. Emergency Preparedness: Identification and Management of Biologic Exposures 51
    Colleen M. Terriff, Jason E. Brouillard, Lisa T. Costanigro, and Jessica S. Oftebro
16. Emergency Preparedness: Identification and Management of Chemical and Radiologic Exposures 53
    Greene Shepherd and Richard B. Schwartz

SECTION 2
Cardiovascular Disorders

Section Editor: Robert L. Talbert

17. Cardiovascular Testing 55
    Richard A. Lange and L. David Hillis
18. Cardiac Arrest 83
    Jeffrey F. Barletta and Jeffrey L. Wilt
19. Hypertension 101
    Joseph J. Saseen and Eric J. Maclaughlin
20. Systolic Heart Failure 137
    Robert B. Parker and Larisa H. Cavallari
21. Diastolic Heart Failure and the Cardiomyopathies 173
    Jean M. Nappi and Robert L. Page II

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

22. Acute Decompensated Heart Failure. 191
Jo E. Rodgers and Craig R. Lee

23. Ischemic Heart Disease. 209
Robert L. Talbert

24. Acute Coronary Syndromes. 241
Sarah A. Spinler and Simon De Denus

25. The Arrhythmias 273
Cynthia A. Sanoski and Jerry L. Bauman

26. Venous Thromboembolism 311
Daniel M. Witt, Edith A. Nutescu, and Stuart T. Haines

27. Stroke. 353
Susan C. Fagan and David C. Hess

28. Dyslipidemia. 365
Robert L. Talbert

29. Peripheral Arterial Disease. 389
Barbara J. Hoeben and Robert L. Talbert

30. Use of Vasopressors and Inotropes in the Pharmacotherapy of Shock. 399
Robert Maclaren, Maria I. Rudis, and Joseph F. Dasta

31. Hypovolemic Shock. 421
Brian L. Erstad

SECTION 3
Respiratory Disorders
Section Editor: Robert L. Talbert

32. Introduction to Pulmonary Function Testing 437
Jay I. Peters and Stephanie M. Levine

33. Asthma 439
H. William Kelly and Christine A. Sorkness

34. Chronic Obstructive Pulmonary Disease 471
Dennis M. Williams and Sharya V. Bourdet

35. Pulmonary Arterial Hypertension 497
Rebecca Moote, Rebecca L. Attridge, and Deborah J. Levine

36. Drug-Induced Pulmonary Disease 511
Hengameh H. Raissy, Michelle Harkins, and Patricia L. Marshik

37. Cystic Fibrosis 525
Chanin C. Wright and Yolanda Y. Vera

SECTION 4
Gastrointestinal Disorders
Section Editor: Joseph T. DiPiro

38. Evaluation of the Gastrointestinal Tract. 539
Keith M. Olsen and Grant F. Hutchins

39. Gastroesophageal Reflux Disease 549
Dianne B. Williams and Robert R. Schade

40. Peptic Ulcer Disease 563
Rosemary R. Berardi and Randolph V. Fugit

41. Inflammatory Bowel Disease 587
Brian A. Hemstreet

42. Nausea and Vomiting 607
Cecily V. DiPiro and Robert J. Ignoffo

43. Diarrhea, Constipation, and Irritable Bowel Syndrome 621
Patricia H. Powell and Virginia H. Fleming

44. Portal Hypertension and Cirrhosis. 639
Julie M. Sease

45. Drug-Induced Liver Disease 659
William R. Kirchain and Rondall E. Allen

46. Pancreatitis 669
Scott Bolesta and Patricia A. Montgomery

47. Viral Hepatitis 685
Paulina Deming

48. Drug Therapy Individualization in Patients with Hepatic Disease and Genetic Alterations in Drug Metabolizing Activity 705
Y. W. Francis Lam

49. Celiac Disease 717
Robert A. Mangione and Priti N. Patel

SECTION 5
Renal Disorders
Section Editor: Gary R. Matzke

50. Clinical Assessment of Kidney Function. 719
Thomas C. Dowling

51. Acute Kidney Injury 741
William Dager and Jenana Halilovic

52. Chronic Kidney Disease: Progression-Modifying Therapies. 767
Vimal K. Derebail, Abhijit V. Kshirsagar, and Melanie S. Joy

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

53. Chronic Kidney Disease: Management of Complications 787
Joanna Q. Hudson

54. Hemodialysis and Peritoneal Dialysis 817
Kevin M. Sowinski and Mariann D. Churchwell

55. Drug-Induced Kidney Disease. 819
Thomas D. Nolin and Jonathan Himmelfarb

56. Glomerulonephritis 837
Alan H. Lau

57. Drug Therapy Individualization for Patients with Chronic Kidney Disease 861
Gary R. Matzke

58. Disorders of Sodium and Water Homeostasis 873
James D. Coyle and Gary R. Matzke

59. Disorders of Calcium and Phosphorus Homeostasis 891
Amy Barton Pai

60. Disorders of Potassium and Magnesium Homeostasis 909
Donald F. Brophy and Jane Frumin

61. Acid-Base Disorders 923
John W. Devlin and Gary R. Matzke

SECTION 6

Neurologic Disorders

Section Editor: Barbara G. Wells

62. Evaluation of Neurologic Illness 943
Susan C. Fagan and Fenwick T. Nichols

63. Alzheimer's Disease. 947
Patricia W. Slattum, Russell H. Swerdlow, and Angela Massey Hill

64. Multiple Sclerosis. 963
Jacquelyn L. Bainbridge and John R. Corboy

65. Epilepsy 979
Susan J. Rogers and Jose E. Cavazos

66. Status Epilepticus. 1007
Stephanie J. Phelps, Collin A. Hovinga, and James W. Wheless

67. Acute Management of the Brain Injury Patient. 1019
Bradley A. Boucher and Shelly D. Timmons

68. Parkinson's Disease 1033
Jack J. Chen, Merlin V. Nelson, and David M. Swope

69. Pain Management 1045
Terry J. Baumann, Jennifer M. Strickland, and Chris M. Herndon

70. Headache Disorders 1061
Deborah S. Minor

SECTION 7

Psychiatric Disorders

Section Editor: Barbara G. Wells

71. Evaluation of Psychiatric Illness 1077
Mark E. Schneiderhan, Leigh Anne Nelson, and Stuart Munro

72. Childhood Disorders. 1087
Julie A. Dopheide and Stephen R. Pliszka

73. Eating Disorders 1101
Steven C. Stoner

74. Substance-Related Disorders: Overview and Depressants, Stimulants, and Hallucinogens. 1113
Paul L. Doering

75. Substance-Related Disorders: Alcohol, Nicotine, and Caffeine 1131
Paul L. Doering and Robin Moorman Li

76. Schizophrenia. 1147
M. Lynn Crismon, Tami R. Argo, and Peter F. Buckley

77. Major Depressive Disorder 1173
Christian J. Teter, Judith C. Kando, and Barbara G. Wells

78. Bipolar Disorder 1191
Shannon J. Drayton

79. Anxiety Disorders I: Generalized Anxiety, Panic, and Social Anxiety Disorders. 1209
Sarah T. Melton and Cynthia K. Kirkwood

80. Anxiety Disorders II: Posttraumatic Stress Disorder and Obsessive-Compulsive Disorder. 1229
Cynthia K. Kirkwood, Lisa B. Phipps, and Barbara G. Wells

81. Sleep Disorders. 1241
John M. Dopp and Bradley G. Phillips

82. Disorders Associated with Intellectual Disabilities 1253
Nancy Brahm, Jerry Mckee, and Douglas Stewart

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

SECTION 8

Endocrinologic Disorders

Section Editor: Robert L. Talbert

83. Diabetes Mellitus 1255
Curtis L. Triplitt and Charles A. Reasner

84. Thyroid Disorders 1303
Jacqueline Jonklaas and Robert L. Talbert

85. Adrenal Gland Disorders 1327
Steven M. Smith and John G. Gums

86. Pituitary Gland Disorders 1345
Amy Heck Sheehan, Jack A. Yanovski, and Karim Anton Calis

SECTION 9

Gynecologic and Obstetric Disorders

Section Editor: Barbara G. Wells

87. Pregnancy and Lactation: Therapeutic Considerations. 1361
Kristina E. Ward and Barbara M. O'Brien

88. Contraception. 1377
Sarah P. Shrader, Kelly R. Ragucci, and Vanessa A. Diaz

89. Menstruation-Related Disorders. 1393
Elena M. Umland, Lara Carson Weinstein, and Edward M. Buchanan

90. Endometriosis. 1409
Deborah A. Sturpe

91. Hormone Therapy in Women. 1417
Sophia N. Kalantaridou, Devra K. Dang, Susan R. Davis, and Karim Anton Calis

SECTION 10

Urologic Disorders

Section Editor: L. Michael Posey

92. Erectile Dysfunction 1437
Mary Lee

93. Benign Prostatic Hyperplasia. 1455
Mary Lee

94. Urinary Incontinence 1467
Eric S. Rovner, Jean Wyman, Thomas Lackner, and David R.P. Guay

SECTION 11

Immunologic Disorders

Section Editor: Gary C. Yee

95. Function and Evaluation of the Immune System 1487
Philip D. Hall, Nicole Weimert Pilch, and Daniel H. Atchley

96. Systemic Lupus Erythematosus and Other Collagen-Vascular Disorders 1505
Jeffrey C. Delafuente and Kimberly A. Cappuzzo

97. Allergic and Pseudoallergic Drug Reactions. 1521
Lynne M. Sylvia and Joseph T. DiPiro

98. Solid-Organ Transplantation. 1537
Heather J. Johnson and Kristine S. Schonder

SECTION 12

Rheumatologic Disorders

Section Editor: L. Michael Posey

99. Osteoporosis and Other Metabolic Bone Diseases. 1559
Mary Beth O'Connell and Sheryl F. Vondracek

100. Rheumatoid Arthritis 1583
Arthur A. Schuna

101. Osteoarthritis 1599
Lucinda M. Buys and Mary Elizabeth Elliott

102. Gout and Hyperuricemia 1621
Michael E. Ernst and Elizabeth C. Clark

SECTION 13

Ophthalmic and Otolaryngological Disorders

Section Editor: L. Michael Posey

103. Glaucoma 1633
Richard G. Fiscella, Timothy S. Lesar, and Deepak P. Edward

104. Allergic Rhinitis 1649
J. Russell May and Philip H. Smith

SECTION 14

Dermatologic Disorders

Section Editor: L. Michael Posey

105. Dermatologic Drug Reactions and Common Skin Conditions 1661
Rebecca M. Law and David T.S. Law

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

106. Acne Vulgaris 1673
Debra J. Sibbald

107. Psoriasis 1693
Rebecca M. Law and Wayne P. Gulliver

108. Atopic Dermatitis 1707
Rebecca M. Law and Po Gin Kwa

SECTION 15
Hematologic Disorders

Section Editor: Gary C. Yee

109. Anemias 1717
Kristen Cook, Beata A. Ineck, and William L. Lyons

110. Coagulation Disorders 1741
Betsy Bickert Poon, Char Witmer, and Jane Pruemer

111. Sickle Cell Disease 1765
C. Y. Jennifer Chan and Reginald Moore

112. Drug-Induced Hematologic Disorders 1781
Christine N. Hansen and Amy F. Rosenberg

SECTION 16
Infectious Diseases

Section Editor: Joseph T. DiPiro

113. Laboratory Tests to Direct Atimicrobial Pharmacotherapy 1797
Michael J. Rybak, Jeffrey R. Aeschlimann, and Kerry L. Laplante

114. Antimicrobial Regimen Selection 1813
David S. Burgess

115. Central Nervous System Infections 1825
Isaac F. Mitropoulos, Elizabeth D. Hermsen, and John C. Rotschafer

116. Lower Respiratory Tract Infections 1845
Martha G. Blackford, Mark L. Glover, and Michael D. Reed

117. Upper Respiratory Tract Infections 1867
Christopher Frei, Bradi Frei, and George Zhanel

118. Influenza 1881
Jessica C. Njoku and Elizabeth D. Hermsen

119. Skin and Soft-Tissue Infections 1893
Douglas N. Fish, Susan L. Pendland, and Larry H. Danziger

120. Infective Endocarditis 1913
Angie Veverka and Michael A. Crouch

121. Tuberculosis 1931
Charles A. Peloquin and Rocsanna Namdar

122. Gastrointestinal Infections and Enterotoxigenic Poisonings 1951
Steven Martin and Rose Jung

123. Intraabdominal Infections 1969
Joseph T. DiPiro and Thomas R. Howdieshell

124. Parasitic Diseases 1981
J. V. Anandan

125. Urinary Tract Infections and Prostatitis 1995
Elizabeth A. Coyle and Randall A. Prince

126. Sexually Transmitted Diseases 2011
Leroy C. Knodel

127. Bone and Joint Infections 2029
Edward P. Armstrong and Allan D. Friedman

128. Severe Sepsis and Septic Shock 2041
S. Lena Kang-Birken and Karla Killgore-Smith

129. Superficial Fungal Infections 2055
Thomas E. R. Brown, Linda D. Dresser, and Thomas W. F. Chin

130. Invasive Fungal Infections 2073
Peggy L. Carver

131. Infections in Immunocompromised Patients 2105
Douglas N. Fish

132. Antimicrobial Prophylaxis in Surgery 2131
Salmaan Kanji

133. Vaccines, Toxoids, and Other Immunobiologics 2147
Mary S. Hayney

134. Human Immunodeficiency Virus Infection 2169
Peter L. Anderson, Thomas N. Kakuda, and Courtney V. Fletcher

SECTION 17
Oncologic Disorders

Section Editor: Gary C. Yee

135. Cancer Treatment and Chemotherapy 2191
Patrick J. Medina and Stacy S. Shord

136. Breast Cancer 2229
Laura Boehnke Michaud, Chad M. Barnett, and Francisco J. Esteva

137. Lung Cancer 2271
Deborah A. Frieze and Val R. Adams

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

138. Colorectal Cancer 2287
Lisa E. Davis, Weijing Sun, and Patrick J. Medina

139. Prostate Cancer 2319
LeAnn B. Norris and Jill M. Kolesar

140. Lymphomas 2333
Alexandre Chan and Gary C. Yee

141. Ovarian Cancer 2361
Judith A. Smith and Judith K. Wolf

142. Acute Leukemias 2377
Betsy Bickert Poon and Dianne M. Brundage

143. Chronic Leukemias 2401
Christopher A. Fausel and Patrick J. Kiel

144. Multiple Myeloma 2417
Timothy R. McGuire and Casey B. Williams

145. Myelodysplastic Syndromes 2431
Julianna A. Burzynski and Tracey Walsh-Chocolaad

146. Renal Cell Carcinoma 2433
Christine M. Walko, Ninh M. La-Beck, and Mark D. Walsh

147. Melanoma 2435
Cindy L. O'Bryant and Jamie C. Poust

148. Hematopoietic Stem Cell Transplantation 2455
Janelle B. Perkins and Gary C. Yee

SECTION 18
Nutritional Disorders

Section Editor: Gary R. Matzke

149. Assessment of Nutrition Status, and Nutrition Requirements 2473
Katherine Hammond Chessman and Vanessa J. Kumpf

150. Medication Administration Considerations with Specialized Nutrition Support 2493
Roland N. Dickerson and Gordon S. Sacks

151. Parenteral Nutrition 2505
Todd W. Mattox and Catherine M. Crill

152. Enteral Nutrition 2527
Vanessa J. Kumpf and Katherine Hammond Chessman

153. Nutritional Considerations in Major Organ Failure 2545
Brian M. Hodges and Mark DeLegge

154. Obesity 2567
Judy T. Chen, Amy Heck Sheehan, Jack A. Yanovski, and Karim Anton Calis

Chapter 15

Thomas E. R. Brown, PharmD
Associate Professor, Leslie Dan Faculty of Pharmacy, University of Toronto and Sunnybrook Health Science Center, Toronto, Ontario
Chapter 129

Dianne M. Brundage, PharmD, FCCP, BCPS, BCOP
Oncology Clinical Pharmacy Specialist, Park Nicollet Health Services Methodist Hospital, Assistant Professor, College of Pharmacy, University of Minnesota, Minneapolis, Minnesota
Chapter 142

Edward M. Buchanan, MD
Thomas Jefferson University, Jefferson Medical College, Philadelphia, Pennsylvania
Chapter 89

Peter F. Buckley, MD
Professor and Chairman, Psychiatry and Health Behavior, Senior Associate Dean for Leadership Development, Medical College of Georgia, Augusta, Georgia
Chapter 76

David S. Burgess, PharmD, FCCP
James T. Doluisio Regents Clinical Professor and Head, Pharmacotherapy, College of Pharmacy, The University of Texas at Austin, Clinical Professor, Department of Medicine, Division of Infectious Diseases, Director, Pharmacotherapy Education and Research Center School of Medicine, The University of Texas Health Science Center, San Antonio, Texas
Chapter 114

Julianna A. Burzynski, PharmD, BCPS, BCOP
Clinical Pharmacy Specialist, Hematology/Oncology, Mayo Clinic, Rochester, Minnesota
Chapter 145

Lucinda M. Buys, PharmD, BCPS
Associate Professor (Clinical), Department of Pharmacy Practice and Science, University of Iowa College of Pharmacy and the Siouxland Medical Education Foundation, Sioux City, Iowa
Chapter 101

Karim Anton Calis, PharmD, MPH, FASHP, FCCP
Adjunct Clinical Investigator, Program in Developmental Endocrinology and Genetics, *Eunice Kennedy Shriver* National Institute of Child Health and Human Development, National Institutes of Health; Clinical Professor, University of Maryland and Virginia Commonwealth University, Richmond, Virginia
Chapters 86, 91, and 154

Kimberly A. Cappuzzo, PharmD, MS, CGP
Senior Regional Medical Liason, Metabolic Bone Team, Scientific Affairs, Amgen, Richmond, Virginia
Chapter 96

Peggy L. Carver, PharmD, FCCP
Associate Professor, Department of Clinical, Social, and Administrative Sciences, The University of Michigan, College of Pharmacy, Clinical Pharmacist, The University of Michigan Health System
Chapter 130

Larisa H. Cavallari, PharmD, FCCP, BCPS
Associate Professor, Department of Pharmacy Practice, College of Pharmacy, University of Illinois at Chicago
Chapters 9 and 20

Jose E. Cavazos, MD, PhD
Associate Professor of Neurology, Pharmacology and Physiology, University of Texas Health Science Center, San Antonio, Texas
Chapter 65

Alexandre Chan, PharmD, BCPS, BCOP
Assistant Professor, Department of Pharmacy, Faculty of Science, National University of Singapore, Clinical Pharmacist, Department of Pharmacy, National Cancer Centre, Singapore, Singapore
Chapter 140

C. Y. Jennifer Chan, PharmD
Clinical Associate Professor of Pediatrics, University of Texas Health Science Center at San Antonio, Clinical Assistant Professor of Pharmacy, University of Texas in Austin, San Antonio, Texas
Chapter 111

Jack J. Chen, PharmD, BCPS, CGP
Associate Professor (Neurology), Movement Disorders Center, Schools of Medicine and Pharmacy, Loma Linda University, Loma Linda, California
Chapter 68

Judy T. Chen, PharmD, BCPS
Clinical Assistant Professor of Pharmacy Practice Purdue University - School of Pharmacy and Pharmaceutical Sciences West Lafayette, Indiana
Chapter 154

Katherine Hammond Chessman, PharmD, FCCP, BCPS, BCNSP
Professor, Department of Pharmacy and Clinical Sciences, South Carolina College of Pharmacy, MUSC Campus, Clinical Pharmacy Specialist, Pediatrics/Pediatric Surgery, Department of Pharmacy Services, Medical University of South Carolina Children's Hospital, Charleston, South Carolina
Chapters 149 and 152

Thomas W. F. Chin*, BScPhm, PharmD, FCSHP
Clinical Pharmacy Specialist/leader- Antimicrobials & Infectious Diseases, St. Michael's Hospital and Assistant Professor, Leslie Dan Faculty of Pharmacy, University of Toronto, Toronto, Ontario
Chapter 129

Elaine Chiquette, PharmD. BCPS
Director, Research & Development Strategic Relations, Amylin Pharmaceuticals, Inc., San Antonio, Texas
Chapter 6

Mariann D. Churchwell, PharmD, BCPS
Assistant Professor, University of Toledo College of Pharmacy, Toledo, Ohio
Chapter 54

Peter A. Chyka, PharmD, FAACT, DABAT
Professor, Department of Clinical Pharmacy; Associate Dean, Knoxville Campus, University of Tennessee College of Pharmacy, Knoxville, Tennessee
Chapter 14

Elizabeth C. Clark, MD, MPH
Assistant Professor, Department of Family Medicine, University of Medicine and Dentistry of New Jersey, Robert Wood Johnson Medical School, New Brunswick, New Jersey
Chapter 102

Kristen Cook, PharmD, BCPS
Assistant Professor, Department of Pharmacy Practice, University of Nebraska Medical Center College of Pharmacy, Clinical Pharmacist, Nebraska-Western Iowa VA Healthcare System, Omaha, Nebraska
Chapter 109

Stephen Joel Coons, PhD
Director, Patient-Reported Outcomes Consortium, Critical Path Institute, Tucson, Arizona
Chapter 2

John R. Corboy, MD
Professor, Neurology, University of Colorado School of Medicine, Co-Director, Rocky Mountain Multiple Sclerosis Center at Anschutz Medical Center, Staff Neurologist, Denver Veteran's Affairs Medical Center, Aurora, Colorado
Chapter 64

Lisa T. Costanigro, PharmD, BCPS
Staff Pharmacist, Paudre Valley Health System, Fort Collins, Colorado
Chapter 15

Elizabeth A. Coyle, PharmD, BCPS
Clinical Associate Professor, University of Houston College of Pharmacy, Houston, Texas
Chapter 125

James D. Coyle
Assistant Professor of Clinical Pharmacy, College of Pharmacy, The Ohio State University, Columbus, Ohio
Chapter 58

Catherine M. Crill, PharmD, BCPS, BCNSP
Associate Professor, Departments of Clinical Pharmacy and Pediatrics, The University of Tennessee Health Science Center, Memphis, Tennessee
Chapter 151

M. Lynn Crismon, PharmD
Dean, James T. Doluisio Regents Chair & Behren's Centennial Professor, College of Pharmacy, The University of Texas at Austin, Austin, Texas
Chapter 76

Michael A. Crouch, PharmD, FASHP, BCPS
Professor and Associate Dean, Gatton College of Pharmacy, East Tennessee State University, Johnson City, Tennessee
Chapter 120

William Dager, PharmD, BCPS, FCSHP, FCCP, FCCM
Pharmacist Specialist, UC Davis Medical Center, Clinical Professor of Pharmacy, UC San Francisco School of Pharmacy, Clinical Professor of Medicine, UC Davis School of Medicine, Clinical Professor of Pharmacy, Touro School of Pharmacy, Sacramento, California
Chapter 51

Devra K. Dang, PharmD, BCPS, CDE
Associate Clinical Professor, University of Connecticut School of Pharmacy, Storrs, Connecticut
Chapter 91

Larry H. Danziger, PharmD
Professor of Pharmacy, College of Pharmacy, University of Illinois at Chicago, Chicago, Illinois
Chapter 119

**Deceased*

Joseph F. Dasta, MSc, FCCM, FCCP
Professor Emeritus, The Ohio State University, Columbus, Ohio, Adjunct Professor, University of Texas, Austin, Texas
Chapter 30

Lisa E. Davis, PharmD, BCPS, BCOP
Associate Professor of Clinical Pharmacy, Philadelphia College of Pharmacy, University of the Sciences in Philadelphia, Philadelphia, Pennsylvania
Chapter 138

Susan R. Davis, MBBS, FRACP, PhD
Department of Medicine, Monash University, Melbourne, Australia
Chapter 91

Jeffrey C. Delafuente, MS, FCCP, FASCP
Associate Dean for Professional Education and Professor of Pharmacotherapy and Outcomes Science, Virginia Commonwealth University School of Pharmacy, Richmond, Virginia
Chapter 96

Mark DeLegge, MD, FACG, CNSP, AGAF, FASGE
Professor of Medicine and Director Digestive Disease Center, Director of Nutrition, Medical University of South Carolina, Charleston, South Carolina
Chapter 153

Paulina Deming, PharmD
University of New Mexico College of Pharmacy, Project ECHO Hepatitis C Community Clinic, Alburquerque, New Mexico
Chapter 47

Simon De Denus, B.Pharm, MSC, PhD
Faculty of Pharmacy, University de Montreal, Montreal Heart Institute, Montreal, Quebec
Chapter 24

Vimal K. Derebail, MD
Clinical Assistant Professor UNC Kidney Center, Division of Nephrology and Hypertension, University of North Carolina at Chapel Hill
Chapter 52

John W. Devlin, PharmD, FCCP, FCCM, BCPS
Associate Professor, Northeastern University School of Pharmacy, Adjunct Associate Professor, Tufts University School of Medicine, Boston, Massachusetts
Chapter 61

Vanessa A. Diaz, MD, MS
Medical University of South Carolina, Department of Family Medicine, Charleston, South Carolina
Chapter 88

Roland N. Dickerson, PharmD, BCNSP, FACN, FCCP
Professor of Clinical Pharmacy, University of Tennessee Health Science Center, Memphis, Tennessee
Chapter 150

Cecily V. DiPiro, PharmD
Consultant Pharmacist, Mt. Pleasant, South Carolina
Chapter 42

Joseph T. DiPiro, PharmD, FCCP
Executive Dean and Professor, South Carolina College of Pharmacy, Medical University of South Carolina and the University of South Carolina
Chapters 97 and 123

Paul L. Doering, MS
Distinguished Service Professor of Pharmacy Practice, College of Pharmacy, University of Florida, Gainesville, Florida
Chapters 74 and 75

Julie A. Dopheide, PharmD, BCPP
Associate Professor, Clinical Pharmacy, Psychiatry and the Behavioral Sciences, University of Southern California Schools of Pharmacy and Medicine, Los Angeles, California
Chapter 72

John M. Dopp, PharmD
Assistant Professor, School of Pharmacy, University of Wisconsin, Madison, Wisconsin
Chapter 81

Thomas C. Dowling, PharmD, PhD, FCP
Associate Professor and Vice Chair, Department of Pharmacy Practice and Science, University of Maryland School of Pharmacy, Baltimore, Maryland
Chapter 50

Shannon J. Drayton, PharmD, BCPP
Assistant Professor, Department of Clinical Pharmacy and Outcomes Research, South Carolina College of Pharmacy, MUSC Campus, Charleston, South Carolina
Chapter 78

Linda D. Dresser, PharmD
Assistant Professor Leslie Dan Faculty of Pharmacy, University of Toronto and University Health Network, Toronto, Canada
Chapter 129

Deepak P. Edward, MD, FACS
Summa Health System and Northeastern Ohio Universities College of Medicine, Akron, Ohio
Chapter 103

Mary Elizabeth Elliott, PharmD, PhD
Associate Professor, Pharmacy Practice Division, University of Wisconsin-Madison School of Pharmacy, Madison, Wisconsin, Clinical Pharmacist, Osteoporosis Clinic, VA Medical Center, Madison, Wisconsin
Chapter 101

Michael E. Ernst, PharmD
Professor (Clinical), Department of Pharmacy Practice and Science, College of Pharmacy; and Department of Family Medicine, Carver College of Medicine, The University of Iowa, Iowa City, Iowa
Chapter 102

Brian L. Erstad, PharmD, FCCM, FCCP, FASHP
Professor, Department of Pharmacy Practice and Science, University of Arizona College of Pharmacy, Tucson Arizona
Chapter 31

Francisco J. Esteva, MD, PhD
Director, Breast Cancer Translational Research Laboratory, Professor, Departments of Breast Medical Oncology and Molecular and Cellular Oncology, University of Texas M.D. Anderson Cancer Center, Houston, Texas
Chapter 136

Susan C. Fagan, PharmD, BCPS, FCCP
Jowdy Professor, Associate Head, Assistant Dean, University of Georgia College of Pharmacy, Augusta, Georgia
Chapters 27 and 62

Christopher A. Fausel, PharmD, BCPS, BCOP
Clinical Director, Oncology Pharmacy Services, Indiana University Simon Cancer Center, Indianapolis, Indiana
Chapter 143

Richard G. Fiscella, PharmD, MPH
Clinical Professor, Department of Pharmacy Practice and Adjunct Assistant Professor, Department of Ophthalmology, University of Illinois at Chicago, Chicago, Illinois
Chapter 103

Douglas N. Fish, PharmD
Professor, Department of Clinical Pharmacy, University of Colorado Denver School of Pharmacy, Clinical Specialist in Infectious Diseases/Critical Care, University of Colorado Hospital, Aurora, Colorado
Chapters 119 and 131

Virginia H. Fleming, PharmD
Clinical Assistant Professor, Department of Clinical and Administrative Pharmacy, University of Georgia College of Pharmacy, Athens, Georgia
Chapter 43

Courtney V. Fletcher, PharmD
Dean and Professor, College of Pharmacy, University of Nebraska Medical Center, Omaha, Nebraska
Chapter 134

Bradi Frei, PharmD, BCPS, BCOP
Assistant Professor, Department of Pharmacy Practice, University of the Incarnate Word, San Antonio, Texas
Chapter 117

Christopher Frei, PharmD, MSc, BCPS
Assistant Professor, Pharmacotherapy Division, College of Pharmacy, The University of Texas at Austin; Clinical Assistant Professor, Department of Medicine, Division of Infectious Diseases and Pharmacotherapy Education & Research Center, School of Medicine, The University of Texas Health Science Center at San Antonio, Texas
Chapter 117

Allan D. Friedman, MD, MPH
Professor and Chair, Division of General Pediatrics, Department of Pediatrics, Virginia Commonwealth University, Richmond, Virginia
Chapter 127

Deborah A. Frieze, PharmD, BCOP
Inpatient Pharmacy Manager, University of Washington Medical Center, Clinical Assistant Professor, University of Washington School of Pharmacy, Seattle, Washington
Chapter 137

Jane Frumin, PharmD
Assistant Professor, Clinical and Administrative Sciences, College of Notre Dame of Maryland School of Pharmacy, Baltimore, Maryland
Chapter 60

Randolph V. Fugit, PharmD, BCPS
Internal Medicine Clinical Specialist, Denver Veterans Affairs Medical Center, Clinical Assistant Professor, Clinical Pharmacy Practice, University of Colorado Denver Health Sciences Center, Denver, Colorado
Chapter 40

Mark L. Glover, BS Pharm, PharmD
Associate Professor and Director, West Palm Beach program, Department of Pharmacy Practice, College of Pharmacy, Nova Southeastern University, Palm Beach Gardens, Florida
Chapter 116

Shelly L. Gray, PharmD, MS
Professor, School of Pharmacy, University of Washington, Seattle, Washington
Chapter 11

David R.P. Guay, PharmD
Professor, Department of Experimental and Clinical Pharmacology, College of Pharmacy, University of Minnesota, Division of Geriatrics, Health Partners Inc., Minneapolis, Minnesota
Chapters 11 and 94

Wayne P. Gulliver, MD, FRCP
Professor of Medicine and Dermatology, and Chair, Discipline of Medicine, Faculty of Medicine, Memorial University of Newfoundland, St. John's Newfoundland and Labrador, Canada
Chapter 107

John G. Gums, PharmD, FCCP
Professor of Pharmacy and Medicine, Associate Chair, Department of Pharmacotherapy and Translational Research, Director of Clinical Research in Family Medicine Departments of Pharmacotherapy and Translational Research and Community Health and Family Medicine, University of Florida
Chapter 85

Stuart T. Haines, PharmD, FCCP, FASHP, FAPHA
Professor, Department of Pharmacy Practice and Science, University of Maryland School of Pharmacy, Baltimore, Maryland and Clinical Pharmacy Specialist, Patient Care Services, West Palm Beach, Virginia Medical Center
Chapter 26

Emily R. Hajjar, PharmD, BCPS, CGP
Associate Professor, Jefferson School of Pharmacy, Thomas Jefferson University, Philadelphia, Pennsylvania
Chapter 11

Jenana Halilovic, PharmD, BCPS
Assistant Professor, Thomas J Long School of Pharmacy, University of the Pacific, Stockton, California and Clinical Pharmacist, UC Davis Medical Center, Sacramento, California
Chapter 51

Philip D. Hall, PharmD, FCCP, BCPS, BCOP
Professor, South Carolina College of Pharmacy, Medical University of South Carolina, Charleston, South Carolina
Chapter 95

Steven M. Handler, Md, PhD
Assistant Professor, University of Pittsburgh School of Medicine, Department of Biomedical Informatics and Division of Geriatric Medicine, Geriatric Research Education and Clinical Center (GRECC), Veterans Affairs Pittsburgh Healthcare Center (VAPHS), Pittsburgh, Pennsylvania
Chapter 11

Joseph T. Hanlon, PharmD, MS
Professor of Medicine, Pharmacy and Epidemiology, University of Pittsburgh and Health Scientist, CHERP/GRECC, Pittsburgh Veterans Affairs Pittsburgh Health System, Pittsburgh, Pennsylvania
Chapter 11

Christine N. Hansen, PharmD
Clinical Pharmacy Specialist, Department of Pharmacy, Lakeland Regional Medical Center, Lakeland, Florida
Chapter 112

Michelle Harkins, MD
Associate Professor of Medicine, Pulmonary and Critical Care, University of New Mexico Health Sciences Center, Albuquerque, New Mexico
Chapter 36

Mary S. Hayney, PharmD, MPH
Professor of Pharmacy (CHS), University of Wisconsin School of Pharmacy
Chapter 133

Thomas K. Hazlet, PharmD, DrPH
Associate Professor, Pharmaceutical Outcomes Research & Policy Program, School of Pharmacy, University of Washington, Seattle, Washington
Chapter 13

Brian A. Hemstreet, PharmD, BCPS
Associate Professor, Department of Clinical Pharmacy, University of Colorado, Denver School of Pharmacy, Aurora, Colorado
Chapter 41

Elizabeth D. Hermsen, PharmD, MBA, BCPS-ID
Antimicrobial Stewardship Program Coordinator, Pharmacy Relations & Clinical Decision Support, The Nebraska Medical Center; Adjunct Assistant Professor, Department of Pharmacy Practice, University of Nebraska Medical Center, College of Pharmacy; Adjunct Assistant Professor, Section of Infectious Diseases, Department of Internal Medicine, University of Nebraska Medical Center, College of Medicine, Omaha, Nebraska
Chapters 115 and 118

Chris M. Herndon, PharmD, BCPS, CPE
Assistant Professor, Department of Pharmacy Practice, Southern Illinois University, Edwardsville School of Pharmacy, Edwardsville, Illinois
Chapter 69

David C. Hess, MD
Professor and Chairman, Department of Neurology, Medical College of Georgia, Augusta, Georgia
Chapter 27

Angela Massey Hill, PharmD, BCPP
Florida A & M University, College of Pharmacy, Professor and Division Director of Pharmacy Practice, Tallahassee, Florida
Chapter 63

L. David Hillis, MD
Professor and Chair, Department of Medicine, University of Texas Health Science Center, San Antonio, Texas
Chapter 17

Jonathan Himmelfarb, MD
Professor of Medicine, Joseph W. Eschbach, MD, Endowed Chair for Kidney Research, Director, Kidney Research Institute, Department of Medicine, Division of Nephrology, University of Washington, Seattle, Washington
Chapter 55

Brian M. Hodges, PharmD, BCPS, BCNSP
Assistant Professor, Department of Clinical Pharmacy, West Virginia University School of Pharmacy, West Virginia
Chapter 153

Barbara J. Hoeben, PharmD, MSPharm, BCPS
Pharmacy Flight Commander, Davis-Monthan Air Force Base, Tucson, Arizona
Chapter 29

Collin A. Hovinga, PharmD
University of Tennessee Health Science Center, LeBonheur Children's Medical Center, Memphis, Tennessee
Chapter 66

Thomas R. Howdieshell, MD, FACS, FCCP
Professor of Surgery, Trauma/Surgical Critical Care, University of New Mexico HSC, Albuquerque, New Mexico
Chapter 123

Joanna Q. Hudson, PharmD, BCPS, FASN
Associate Professor, Departments of Clinical Pharmacy and Medicine (Nephrology), The University of Tennessee Health Science Center, Memphis, Tennessee
Chapter 53

Grant F. Hutchins, MD
Assistant Professor Gastroenterology/Hepatology, Director of Advanced Endoscopy, University of Nebraska Medical Center, Omaha, Nebraska
Chapter 38

Robert J. Ignoffo, PharmD
Touro University, Vallejo, California
Chapter 42

Beata A. Ineck, PharmD, BCPS, CDE
Home Based Primary Care, Clinical Pharmacist, Boise VA Medical Center, Boise, Idaho
Chapter 109

Arthur A. Islas, MD, MPH, CAQ–Sports Medicine, FAWM
Associate Professor, Department of Family & Community Medicine, Paul L. Foster School of Medicine, Texas Tech University Health Science Center, El Paso, Texas
Chapter 4

Heather J. Johnson, PharmD, BCPS, FASN
Assistant Professor, Department of Pharmacy and Therapeutics, University of Pittsburgh School of Pharmacy, Clinical Pharmacist, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Chapter 98

Jacqueline Jonklaas, MD, PhD
Associate Professor, Division of Endocrinology, Georgetown University Medical Center, Washington DC
Chapter 84

Melanie S. Joy, PharmD, PhD, FCCP, FASN
Associate Professor, School of Medicine, Division of Nephrology & Hypertension, UNC Kidney Center, and Associate Professor, School of Pharmacy, Division of Pharmacotherapy and Experimental Therapeutics, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina
Chapter 52

Rose Jung, PharmD, MPH, BCPS
Visiting Associate Professor, Department of Pharmacy Practice, University of Toledo, College of Pharmacy, Toledo, Ohio
Chapter 122

Thomas N. Kakuda, PharmD
Director, Clinical Pharmacology, Tibotec, Inc., Titusville, New Jersey
Chapter 134

Sophia N. Kalantaridou, MD, PhD
Associate Professor, Department of Obstetrics and Gynecology, Division of Reproductive Endocrinology, University of Ioannina Medical School, Ioannina, Greece
Chapter 91

Judith C. Kando, PharmD, BCPP
Ortho-McNeil Janssen Scientific Affairs, LLC, Tewksbury, Massachusetts
Chapter 77

S. Lena Kang-Birken, PharmD, FCCP
Associate Professor, Department of Pharmacy Practice, Thomas J. Long School of Pharmacy and Health Sciences, University of The Pacific, Stockton, California
Chapter 128

Salmaan Kanji, PharmD
Clinical Pharmacy Specialist (ICU), Department of Pharmacy and Critical Care, The Ottawa Hospital, Associate Scientist, Clinical Epidemiology Program, Ottawa Hospital Institute, Ottawa, Ontario
Chapter 132

H. William Kelly, PharmD
Professor Emeritus Pediatrics, University of New Mexico Health Sciences Center, Albuquerque, New Mexico
Chapter 33

Patrick J. Kiel, PharmD, BCPS, BCOP
Clinical Pharmacy Specialist, Hematology/Stem Cell Transplant, Indiana University Simon Cancer Center, Indianapolis, Indiana
Chapter 143

Karla Killgore-Smith, PharmD, BCPS
Clinical Pharmacist, Santa Barbara Cottage Hospital, Adjunct Professor of Pharmacy, University of Pacific, Santa Barbara, California
Chapter 128

William R. Kirchain, PharmD, CDE
Wilbur and Mildred Robichaux Endowed Professor, Division of Clinical and Administrative Sciences, College of Pharmacy, Xavier University of Louisiana, New Orleans, Louisiana
Chapter 45

Cynthia K. Kirkwood, PharmD, BCPP
Associate Professor of Pharmacy, Vice Chair for Education, Department of Pharmacotherapy and Outcome Science, School of Pharmacy, Virginia Commonwealth University, Richmond, Virginia
Chapters 79 and 80

Leroy C. Knodel, PharmD
Associate Professor, Department of Surgery, The University of Texas Health Science Center, San Antonio, San Antonio, Texas, Clinical Associate Professor, College of Pharmacy, The University of Texas at Austin, Austin, Texas
Chapter 126

Jill M. Kolesar, PharmD, BCPS, FCCP
Professor of Pharmacy, University of Wisconsin, School of Pharmacy, University of Wisconsin Carbone Cancer Center, Madison, Wisconsin
Chapter 139

Sunil Kripalani, MD, MSc
Associate Professor and Chief, Section of Hospital Medicine, Vanderbilt University, Nashville, Tennessee
Chapter 3

Abhijit V. Kshirsagar, MD, MPH
Associate Professor of Medicine Division of Nephrology and Hypertension, UNC Kidney Center, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina
Chapter 52

Vanessa J. Kumpf, PharmD, BCNSP
Clinical Specialist, Nutrition Support, Vanderbilt University Medical Center, Nashville, Tennessee
Chapters 149 and 152

Po Gin Kwa, MD, FRCP
Clinical Associate Professor, Faculty of Medicine, Memorial University of Newfoundland, St. John's Newfoundland, Canada
Chapter 108

Ninh M. La-Beck, PharmD
Assistant Professor, Center for Immunotherapeutic Research and Department of Pharmacy Practice, School of Pharmacy, Texas Tech University Health Sciences Center, Abilene, Texas
Chapter 146

Thomas Lackner, PharmD
Experimental and Clinical Pharmacology, College of Pharmacy, University of Minnesota, Minneapolis, Minnesota
Chapter 94

Y. W. Francis Lam, PharmD, FCCP
Professor of Pharmacology, University of Texas Health Science Center at San Antonio, Associate Professor of Medicine, University of Texas Health Science Centre at San Antonio, Clinical Associate Professor of Pharmacy, University of Texas at Austin, Austin, Texas
Chapters 9 and 48

Richard A. Lange, MD, MBA
Professor and Executive Vice Chairman, Department of Medicine, The University of Texas Health Science Center, San Antonio, Texas
Chapter 17

Kerry L. Laplante, PharmD
University of Rhode Island, Department of Pharmacy Practice, Infectious Diseases Research Laboratory, Providence Veterans Affairs Medical Center, Division of Infectious Diseases, Department of Medicine, Warren Alpert Medical School of Brown University, Providence, Rhode Island
Chapter 113

Alan H. Lau, PharmD, FCCP
Professor of Pharmacy Practice and Director, International Clinical Pharmacy Education College of Pharmacy University of Illinois at Chicago, Chicago, Illinois
Chapter 56

David T.S. Law, BSc, MD, PhD, CCFP
Assistant Professor, Department of Community and Family Medicine, University of Toronto, and Staff Physician, Department of Family Practice, The Scarborough Hospital and Rouge Valley Health System, Scarborough, Ontario, Canada
Chapter 105

Rebecca M. Law, PharmD
Associate Professor, School of Pharmacy and Discipline of Family Medicine, Faculty of Medicine, Memorial University of Newfoundland, St. John's, Newfoundland, Canada
Chapters 105, 107, and 108

Craig R. Lee, PharmD, PhD
Assistant Professor, Division of Pharmacotherapy and Experimental Therapeutics, UNC Eshelman School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina
Chapter 22

Mary Lee, PharmD, BCPS, FCCP
Professor of Pharmacy Practice, Chicago College of Pharmacy, Vice President and Chief Academic Officer, Pharmacy and Health Sciences Education, Midwestern University, Downers Grove, Illinois
Chapters 92 and 93

Timothy S. Lesar, PharmD
Director of Clinical Pharmacy Service, Albany Medical Center, Albany, New York
Chapter 103

Deborah J. Levine
Associate Professor of Medicine, Division of Pulmonary and Critical Care, University of Texas, San Antonio, San Antonio, Texas
Chapter 35

Stephanie M. Levine, MD
Professor of Medicine, Division of Pulmonary Diseases and Critical Care Medicine, University of Texas Health Science Center, San Antonio, San Antonio, Texas
Chapter 32

Robin Moorman Li, PharmD
Assistant Professor Department of Pharmacotherapy and Translational Research, College of Pharmacy, University of Florida, Gainesville, Florida
Chapter 75

Jeffrey D. Little, PharmD, MPH
Pharmacy Manager, Finance and Ancillary Services, Children's Mercy Hospital and Clinics, Kansas City, Missouri
Chapter 5

Amanda M. Loya, PharmD
Clinical Assistant Professor, University of Texas at El Paso College of Health Sciences and University of Texas at Austin College of Pharmacy, El Paso, Texas
Chapter 4

William L. Lyons, MD
Associate Professor, Section of Geriatrics, Department of Internal Medicine, University of Nebraska Medical Center, Omaha, Nebraska
Chapter 109

George E. MacKinnon III, BS, MS, PhD, RPh, FASHP
Founding Dean and Professor, College of Pharmacy, Roosevelt University, Schaumburg, Illinois
Chapter 7

Neil J. MacKinnon, PhD, FCSHP
Associate Director for Research and Professor, College of Pharmacy, Dalhousie University, Halifax, Nova Scotia, Canada
Chapter 7

Robert MacLaren, BSc, PharmD, FCCM, FCCP
Associate Professor, Department of Clinical Pharmacy, School of Pharmacy, University of Colorado Denver, Aurora, Colorado
Chapter 30

Eric J. MacLaughlin, PharmD, FCCP, BCPS
Associate Professor and Head of Adult Medicine, Department of Pharmacy Practice, Texas Tech University Health Sciences Center School of Pharmacy, Amarillo, Texas
Chapter 19

Robert A. Mangione, EdD, RPh
Dean and Professor, St. John's University, College of Pharmacy and Allied Health Professions, Queens, New York
Chapter 49

Scott M. Mark, PharmD, MS, MEd, MPH, MBA, FASHP, FACHE, FABC
Director of Pharmacy, University of Pittsburgh Medical Center, Director, Pharmacy Practice Management Residency, Associate Professor and Vice Chair, University of Pittsburgh School of Pharmacy, Pittsburgh, Pennsylvania
Chapter 5

Patricia L. Marshik, PharmD
Associate Professor, Department of Pharmacy Practice, College of Pharmacy, University of New Mexico, Albuquerque, New Mexico
Chapter 36

Steven Martin, PharmD, BCPS, FCCP, FCCM
Professor and Chairman, Department of Pharmacy Practice, College of Pharmacy, The University of Toledo, Toledo, Ohio
Chapter 122

Todd W. Mattox, PharmD, BCNSP
Nutrition Support Team Lead, Moffitt Cancer Center and Research Institute, Tampa, Florida
Chapter 151

Gary R. Matzke, PharmD, FCP, FCCP, FASN, FNAP
Professor and Associate Dean for Clinical Research and Public Policy, School of Pharmacy, Virginia Commonwealth University-MCV Campus, Richmond, Virginia
Chapters 57, 58, and 61

J. Russell May, PharmD, FASHP
Clinical Professor, Department of Clinical and Administrative Pharmacy, University of Georgia, College of Pharmacy, Medical College of Georgia Campus, Augusta, Georgia
Chapter 104

Timothy R. McGuire, PharmD, FCCP, BCOP
Associate Professor, Department of Pharmacy Practice, College of Pharmacy, University of Nebraska Medical Center, Omaha, Nebraska
Chapter 144

Jerry McKee, PharmD, MS, BCPP
Pharmacy Clinical Practice Specialist, University of Texas Medical Branch, Correctional Managed Care, Huntsville, Texas
Chapter 82

Patrick J. Medina, PharmD, BCOP
Associate Professor, University of Oklahoma, College of Pharmacy, Oklahoma City, Oklahoma
Chapters 135 and 138

Sarah T. Melton, PharmD, BCPP, CGP
Director of Addiction Outreach, Associate Professor of Pharmacy Practice, Appalachian College of Pharmacy, Oakwood, Virginia
Chapter 79

Laura Boehnke Michaud, PharmD, BCOP, FASHP
Manager, Clinical Pharmacy Services, The University of Texas M. D. Anderson Cancer Center, Adjunct Assistant Professor of Pharmacy Practice, University of Houston, College of Pharmacy, Houston, Texas
Chapter 136

Deborah S. Minor, PharmD
Associate Professor, Department of Medicine, School of Medicine, University of Mississippi Medical Center, Assistant Professor, Department of Pharmacy Practice, University of Mississippi, Jackson, Mississippi
Chapter 70

Isaac F. Mitropoulos, PharmD
Ortho-McNeil Janssen Scientific Affairs, Cary, North Carolina
Chapter 115

Patricia A. Montgomery, PharmD
Clinical Pharmacy Specialist, Mercy General Hospital, Sacramento, California
Chapter 46

Reginald Moore, MD
Clinical Associate Professor, University of Texas Health Science Center, San Antonio, Texas, Director, Regional Sickle Cell Program, San Antonio, Texas
Chapter 111

Rebecca Moote, PharmD, MSc, BCPS
Assistant Professor, Department of Pharmacy Practice, Regis University School of Pharmacy, Denver, Colorado
Chapter 35

Stuart Munro, MD
Professor and Chair, Department of Psychiatry, School of Medicine, University of Missouri-Kansas City, Kansas City, Missouri
Chapter 71

Milap C. Nahata, PharmD, MS, FCCP
Professor of Pharmacy, Pediatrics and Internal Medicine, Division Chair, Pharmacy Practice and Administration, College of Pharmacy, Ohio State University, Associate Director of Pharmacy, Ohio State University Medical Center, Columbus, Ohio
Chapter 10

Rocsanna Namdar, PharmD, BCPS
Assistant Professor, University of Colorado, Aurora, Colorado
Chapter 121

Jean M. Nappi, BS, PharmD, FCCP, BCPS
Professor of Clinical Pharmacy and Outcome Sciences, South Carolina College of Pharmacy -MUSC Campus Professor of Medicine, Medical University of South Carolina, Charleston, South Carolina
Chapter 21

Leigh Anne Nelson, PharmD, BCPP
Assistant Professor, Division of Pharmacy Practice and Administration, University of Missouri-Kansas City School of Pharmacy, Kansas City, Missouri
Chapter 71

Merlin V. Nelson, PharmD, MD
Neurologist, Affiliated Community Medical Centers, Willmor, Minnesota
Chapter 68

Fenwick T. Nichols III, MD, FACP, FAAN, FAHA
Professor, Neurology; Professor, Radiology; Medical College of Georgia, Augusta, Georgia
Chapter 62

Jessica C. Njoku, PharmD, BCPS
Pharmacy Relations & Clinical Decision Suport, The Nebraska Medical Center, University of Nebraska Medical Center, College of Pharmacy, Department of Pharmacy Practice, Omaha, Nebraska
Chapter 118

Thomas D. Nolin, PharmD, PhD
Assistant Professor, Department of Pharmacy and Therapeutics, and Department of Medicine Renal Electrolyte Division, University of Pittsburgh Schools of Pharmacy and Medicine, Pittsburgh, Pennsylvania
Chapter 55

LeAnn B. Norris, PharmD, BCPS, BCOP
Assistant Professor, Department of Clinical Pharmacy and Outcomes Sciences, South Carolina College of Pharmacy, University of South Carolina Campus, Columbia, South Carolina
Chapter 139

Edith A. Nutescu, PharmD, FCCP
Clinical Professor, Department of Pharmacy Practice and Center for Pharmacoeconomic Research, Director, Antithrombosis Center, The University of Illinois at Chicago, College of Pharmacy & Medical Center, Chicago, Illinois
Chapter 26

Barbara M. O'Brien, MD
Assistant Professor Obstetrics and Gynecology, Warren Alpert School of Medicine at Brown University, Director of Maternal Fetal Medicine; Director of Perinatal Genetics, Providence Rhode Island
Chapter 87

Cindy L. O'Bryant, PharmD, FCCP, BCOP
Associate Professor, Department of Clinical Pharmacy, School of Pharmacy, University of Colorado Denver, Aurora, Colorado
Chapter 147

Mary Beth O'Connell, PharmD, BCPS, FASHP, FCCP
Associate Professor, Pharmacy Practice Department, Eugene Applebaum College of Pharmacy and Health Systems, Wayne State University, Detroit, Michigan
Chapter 99

Jessica S. Oftebro, PharmD, BA
Kelley-Ross Pharmacy, Seattle, Washington
Chapter 15

Keith M. Olsen, PharmD, FCCP, FCCM
Professor and Chair, Department of Pharmacy Practice, University of Nebraska Medical Center, Omaha, Nebraska
Chapter 38

Robert L. Page II, PharmD, MSPH, FCCP, FAHA, FASHP, BCPS, CGP
Associate Professor of Clinical Pharmacy and Physical Medicine, University of Colorado Denver Schools of Pharmacy and Medicine, Clinical Specialist, Division of Cardiology, University of Colorado Hospital, Aurora, Colorado
Chapter 21

Amy Barton Pai, PharmD, BCPS, FCCP, FASN
Associate Professor, Department of Pharmacy Practice, ANephRx-Albany Nephrology Pharmacy, Albany College of Pharmacy and Health Sciences, Albany, New York
Chapter 59

Robert B. Parker, PharmD, FCCP
Professor, University of Tennessee College of Pharmacy, Department of Clinical Pharmacy, Memphis, Tennessee
Chapter 20

Priti N. Patel, PharmD, BCPS
Assistant Clinical Professor, College of Pharmacy and Alliec Health Professions, St. John's University, Queens, New York
Chapter 49

Charles A. Peloquin
Professor and Director of Infectious Disease Pharmacokinetics Laboratory, College of Pharmacy, and Emerging Infectious Pathogens Institute, University of Florida, Gainesville, Florida
Chapter 121

Susan L. Pendland, MS, PharmD
St. Joseph Beren Hospital, Beren Kentucky, University of Illinois at Chicago, Department of Pharmacy Practice, Chicago, Illinois
Chapter 119

Janelle B. Perkins, PharmD, BCOP
Assistant Member, Blood and Marrow Transplantation, H. Lee Moffitt Cancer Center and Research Institute, Tampa, Florida
Chapter 148

Jay I. Peters, MD
Professor of Medicine, Division of Pulmonary and Critical Care, University of Texas Health Science Center at San Antonio, San Antonio, Texas
Chapter 32

Stephanie J. Phelps, PharmD, BCPS
Professor, Clinical Pharmacy and Pediatrics, University of Tennessee Health Science Center, College of Pharmacy, Memphis, Tennessee
Chapter 66

Bradley G. Phillips, PharmD, BCPS, FCCP
Millikan-Reeve Professor and Head, Department of Clinical and Administrative Pharmacy, University of Georgia College of Pharmacy, Athens, Georgia
Chapter 81

Lisa B. Phipps, PharmD, PhD
Assistant Professor, Department of Pharmacotherapy & Outcomes Science, Virginia Commonwealth University, Richmond, Virginia
Chapter 80

Nicole Weimert Pilch, PharmD, MSCR, BCPS
Clinical Specialist, Solid Organ Transplantation, Clinical Assistant Professor, Department of Pharmacy and Clinical Sciences, South Carolina College of Pharmacy, MUSC Campus, Medical University of South Carolina, Department of Pharmacy Services, Charleston, South Carolina
Chapter 95

Stephen R. Pliszka, MD
Professor and Vice Chair, Chief Division of Child and Adolescent Psychiatry, Department of Psychiatry, The University of Texas Health Science, Center at San Antonio, San Antonio, Texas
Chapter 72

Betsy Bickert Poon, PharmD, FCCP
Clinical Specialist, Pediatric Hematology/Oncology, Florida Hospital for Children, Clinical Assistant Professor, University of Florida College of Pharmacy, Orlando, Florida
Chapters 110 and 142

L. Michael Posey, BSPharm
Editorial Director, Periodicals Department, American Pharmacists Association, Washington, DC
Chapter 6

Jamie C. Poust, PharmD, BCOP
Oncology Clinical Specialist, Department of Pharmacy, University of Colorado Hospital, Aurora, Colorado
Chapter 147

Patricia H. Powell, PharmD, BCPS
Assistant Professor, Clinical Pharmacy and Outcomes Sciences, South Carolina College of Pharmacy, University of South Carolina Campus, Columbia, South Carolina
Chapter 43

Randall A. Prince, PharmD, PhD
Professor, University of Houston College of Pharmacy, Houston, Texas
Chapter 125

Jane Pruemer, PharmD, BCOP, FASHP
Professor of Pharmacy Practice, Oncology Clinical Pharmacy Specialist, James L. Winkle College of Pharmacy, University of Cincinnati, Cincinnati, Ohio
Chapter 110

Kelly R. Ragucci, PharmD, FCCP, BCPS, CDE
Associate Professor, Clinical Pharmacy and Outcomes Sciences, South Carolina College of Pharmacy, Medical University of South Carolina Campus, Charleston, South Carolina
Chapter 88

Hengameh H. Raissy, PharmD
Department of Pediatrics, School of Medicine, University of New Mexico, Alburquerque, Mew Mexico
Chapter 36

Charles A. Reasner, MD
Professor of Medicine/Diabetes, University of Texas Health Science Center at San Antonio and Medical Director at the Texas Diabetes Institute, San Antonio, Texas
Chapter 83

Michael D. Reed, PharmD, FCCP, FCP
Director, Division of Clinical Pharmacology and Toxicology, and the Rebecca D. Considine Research Institute, Children's Hospital Medical Center of Akron and Professor & Associate Chair, Department of Pediatrics NEOUCOM, Akron, Ohio
Chapter 116

José O. Rivera, PharmD
Clinical Professor, University of Texas at El Paso College of Health Sciences and University of Texas at Austin College of Pharmacy, El Paso, Texas
Chapter 4

Jo E. Rodgers, PharmD, FCCP, BCPS
Clinical Associate Professor, Department of Pharmacotherapy and Experimental Therapeutics, Eshelman School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina
Chapter 22

Susan J. Rogers, PharmD, BCPS
Assistant Clinical Professor, University of Texas at Austin; Clinical Pharmacy Specialist Neurology, South Texas Healthcare System, Audie L. Murphy Veterans Hospital, San Antonio, Texas
Chapter 65

Amy F. Rosenberg, PharmD, BCPS
Clinical Pharmacy Specialist, Shands at the University of Florida, Gainesville, Florida
Chapter 112

John C. Rotschafer, PharmD, FCCP
Professor, Experimental and Clinical Pharmacology, College of Pharmacy, Minneapolis, Minnesota
Chapter 115

Eric S. Rovner, MD
Professor of Urology, Department of Urology, Medical University of South Carolina, Charleston, South Carolina
Chapter 94

Maria I. Rudis, PharmD, BScPharm
Clinical Pharmacy Specialist - Emergency Medicine, Program Director, Emergency Medicine Pharmacy Residency, Chair, Research Committee, Department of Pharmacy Services, St. Mary's Hospital, Mayo Clinic, Rochester, Minnesota
Chapter 30

Michael J. Rybak, PharmD, MPH
Associate Dean for Research, Professor of Pharmacy and Medicine, Director, Anti-Infective Research Laboratory Department of Pharmacy Practice, Eugene Applebaum College of Pharmacy, Wayne State University, Detroit, Michigan
Chapter 113

Gordon S. Sacks, PharmD, BCNSP
Professor and Head, Department of Pharmacy Practice, Harrison School of Pharmacy, Auburn University, Auburn, Alabama
Chapter 150

Cynthia A. Sanoski, PharmD, BCPS, FCCP
Chair, Department of Pharmacy Practice, Associate Professor, Jefferson School of Pharmacy, Thomas Jefferson University, Philadelphia, Pennsylvania
Chapter 25

Joseph J. Saseen, PharmD
Professor, Clinical Pharmacy and Family Medicine, Schools of Pharmacy and Medicine University of Colorado Denver, Aurora, Colorado
Chapter 19

Robert R. Schade, MD, FACP, AGAF, FACG, FASGE
Medical College of Georgia, Professor of Medicine, Chief, Section of Gastroenterology/Hepatology Medical College of Georgia, Augusta, Georgia
Chapter 39

Mark E. Schneiderhan, PharmD, BCPP
University of Minnesota College of Pharmacy, Duluth, Department of Pharmacy Practice and Pharmaceutical Sciences, Human Development Center, Duluth, Minnesota
Chapter 71

Kristine S. Schonder, PharmD
Assistant Professor, Pharmacy and Therapeutics, University of Pittsburgh School of Pharmacy; Clinical Pharmacist, Thomas E. Starzl Transplantation Institute, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Chapter 98

Arthur A. Schuna, MS, FASHP
Clinical Coordinator, William S. Middleton VA Medical Center, Clinical Professor, University of Wisconsin School of Pharmacy, Madison, Wisconsin
Chapter 100

Richard B. Schwartz, MD
Associate Professor, Department of Emergency Medicine, Medical College of Georgia, Augusta, Georgia
Chapter 16

Julie M. Sease, PharmD, BCPS, CDE
Associate Professor of Pharmacy Practice, Department of Pharmacy Practice, Presbyterian College School of Pharmacy, Clinton, South Carolina
Chapter 44

Amy Heck Sheehan, PharmD
Associate Professor, Department of Pharmacy Practice, Purdue University School of Pharmacy and Pharmaceutical Sciences, Indianapolis, Indiana
Chapters 86 and 154

Greene Shepherd, PharmD
Clinical Associate Professor, College of Pharmacy, University of Georgia, Augusta, Georgia
Chapter 16

Stacy S. Shord, PharmD, BCOP, FCCP
Reviewer, Office of Clinical Pharmacology, Office of Translational Science, Center for Drug Evaluation and Research, U.S. Food and Drug Administration, Silver Spring, Maryland
Chapter 135

Sarah P. Shrader PharmD, BCPS, CDE
Assistant Professor, Department of Clinical Pharmacy and Outcomes Sciences, South Carolina College of Pharmacy -MUSC Campus, Charleston, South Carolina
Chapter 88

Jeri J. Sias, PharmD, MPH
Clinical Associate Professor, University of Texas at El Paso/ UT Austin Cooperative Pharmacy Program, Adjunct Clinical Assistant Professor, Department of Family and Community Medicine, Texas Tech University Health Sciences Center - El Paso, El Paso, Texas
Chapter 4

Debra J. Sibbald, BScPhm, ACPR, MA, PhD
Senior Tutor, Division of Pharmacy Practice, Leslie Dan Faculty of Pharmacy, University of Toronto, Toronto, Ontario, Canada
Chapter 106

Patricia W. Slattum, PharmD, PhD
Associate Professor of Pharmacy, Geriatric Pharmacotherapy Program, Virginia Commonwealth University, School of Pharmacy, Richmond, Virginia
Chapter 63

Judith A. Smith, PharmD, BCOP, FCCP, FISOPP
Associate Professor and Director of Pharmacology Research, Department of Gynecologic Oncology, Division of Surgery, The University of Texas M.D. Anderson Cancer Center, Houston, Texas
Chapter 141

Philip H. Smith, MD
Assistant Professor of Medicine, Medical College of Georgia, Director of Allergy Services, Charlie Norwood VA Hospital, Augusta, Georgia
Chapter 104

Steven M. Smith, PharmD
Postdoctoral Fellow, Departments of Pharmacotherapy and Translational Research and Community Health and Family Medicine, Colleges of Pharmacy and Medicine, University of Florida, Gainesville, Florida
Chapter 85

Christine A. Sorkness, PharmD
Professor of Pharmacy and Medicine, University of Wisconsin, Madison, Wisconsin
Chapter 33

Kevin M. Sowinski, PharmD, FCCP
Professor, Department of Pharmacy Practice, School of Pharmacy and Pharmaceutical Sciences, Purdue University, West Lafayette and Indianapolis, Indiana, Adjunct Professor, Department of Medicine, School of Medicine, Indiana University, Indianapolis, Indiana
Chapter 54

Sarah A. Spinler, PharmD, FCCP, FAHA, FASHP, BCPS (AQ Cardiology)
Professor of Clinical Pharmacy, Residency Programs Coordinator, Philadelphia College of Pharmacy, University of the Sciences in Philadelphia, Philadelphia, Pennsylvania
Chapter 24

Catherine I. Starner, PharmD, BCPS, CGP
Senior Clinical Pharmacist, Prime Theapeutics, LLC. Eagan, Minnesota
Chapter 11

Andy Stergachis, PhD, RPh
Professor of Epidemiology and Global Health, Adjunct Professor of Pharmacy & Health Services, Director, Global Medicines Program, School of Public Health, University of Washington, Seattle, Washington
Chapter 13

Douglas Stewart, DO, MPH
Associate Professor, Department of Pediatrics, University of Oklahoma College of Medicine, Tulsa, Oklahoma
Chapter 82

Steven C. Stoner, PharmD, BCPP
Chair and Clinical Professor of Psychiatric Pharmacy, UMKC School of Pharmacy, Division of Pharmacy Practice and Administration, Kansas City, Missouri
Chapter 73

Jennifer M. Strickland, PharmD, BCPS
Co-Director, Center of Advancing Quality of Life, Director, Pharmacy, Pain & Palliative Care Specialist, Lakeland Regional Medical Center, Lakeland, Florida
Chapter 69

Deborah A. Sturpe, PharmD, BCPS
Associate Professor, Department of Pharmacy Practice and Science, University of Maryland School of Pharmacy, Baltimore, Maryland
Chapter 90

Weijing Sun, MD
Associate Professor of Medicine, Director, GI Medical Oncology Program, Abramson Cancer Center, University of Pennsylvania, Philadelphia, Pennsylvania
Chapter 138

Russell H. Swerdlow, MD
Professor, Neurology and Molecular & Integrative Physiology, University of Kansas School of Medicine, Kansas City, Kansas
Chapter 63

David M. Swope, MD
Associate Professor of Neurology, Loma Linda University, Loma Linda, California
Chapter 68

Lynne M. Sylvia, PharmD
Clinical Pharmacy Specialist, Tufts Medical Center, Adjunct Clinical Professor, Northeastern University, School of Pharmacy, Boston, Massachusetts
Chapter 97

Carol Taketomo, PharmD
Director of Pharmacy, Children's Hospital Los Angeles, Adjunct Assistant Professor of Pharmacy Practice, University of Southern California, School of Pharmacy, Los Angeles, California
Chapter 10

Robert L. Talbert, PharmD, FCCP, BCPS, FAHA
SmithKline Professor, College of Pharmacy, The University of Texas at Austin, Professor, School of Medicine, University of Texas Health Science Center at San Antonio, Texas
Chapters 23, 28, 29, and 84

Colleen M. Terriff, PharmD
Clinical Associate Professor, Washington State University, College of Pharmacy, Deaconess Medical Center Pharmacy Department, Spokane, Washington
Chapter 15

Christian J. Teter, PharmD, BCPP
Assistant Professor, Pharmacy Practice, School of Pharmacy, Northeastern University, Boston, Massachusetts, Clinician-Researcher, Alcohol and Drug Abuse Treatment Program, McLean Hospital, Belmont, Massachusetts
Chapter 77

Shelly D. Timmons, MD, PhD, FACS
Associate Professor and Chief of Neurotrauma Division, Department of Neurosurgery, University of Tennessee Health Science Center, Semmes-Murphey Neurologic and Spine Institute, Memphis, Tennessee
Chapter 67

Lisa Sanchez Trask, PharmD
Executive Manager, Clinical Science & Outcomes Manager, Takeda Pharmaceuticals America, Inc. Denver, Colorado
Chapter 1

Curtis L. Triplitt, PharmD, CDE
Clinical Assistant Professor, Department of Medicine, Division of Diabetes, University of Texas Health Science Center at San Antonio, Texas
Chapter 83

Elena M. Umland, PharmD
Associate Dean for Academic Affairs, Associate Professor of Pharmacy Practice Jefferson School of Pharmacy, Thomas Jefferson University, Philadelphia, Pennsylvania
Chapter 89

Ulysses J. Urquidi, MD, MS, FAAFP
Associate Professor and Chief, Division of Community Medicine, Texas Tech Health Sciences Center, Paul L. Foster School of Medicine, Department of Family and Community Medicine, El Paso, Texas
Chapter 4

Yolanda Y. Vera, PharmD
Pediatric Patient Care Pharmacist, Department of Pharmacy, The Children's Hospital at Scott & White, Temple, Texas
Chapter 37

Angie Veverka, PharmD
Associate Professor of Pharmacy, Wingate University School of Pharmacy, Wingate, North Carolina
Chapter 120

Sheryl F. Vondracek, PharmD
Associate Professor, Department of Clinical Pharmacy, School of Pharmacy, University of Colorado Denver, Aurora, Colorado
Chapter 99

Christine M. Walko, PharmD, BCOP
Clinical Assistant Professor, Division of Pharmacotherapy and Experimental Therapeutics, Institute of Pharmacogenomics and Individualized Therapy, University of North Carolina School of Pharmacy, Chapel Hill, North Carolina
Chapter 146

Mark D. Walsh, PharmD
Hematology/Oncology Fellow, Division of Pharmacotherapy and Experimental Therapeutics, UNC Eshelman School of Pharmacy, University of North Carolina, Chapel Hill, North Carolina
Chapter 146

Tracey Walsh-Chocolaad, PharmD, BCOP
Clinical Pharmacist, Outpatient Stem Cell Transplantation, National Heart, Lung and Blood Institute, National Institutes of Health, Bethesda, Maryland
Chapter 145

Kristina E. Ward, BS, PharmD, BCPS
Clinical Assistant Professor of Pharmacy Practice, Director, Drug Information Services, College of Pharmacy, University of Rhode Island, Kingston, Rhode Island
Chapter 87

Robert J. Weber, PharmD, MS, BCPS, FASHP
Senior Director, Pharmaceutical Services, and Assistant Dean for Medical Center Affairs, The Ohio State University Medical Center and College of Pharmacy, Columbus, Ohio
Chapter 5

Lara Carson Weinstein, MD
Assistant Professor, Department of Family and Community Medicine, Thomas Jefferson University, Philadelphia, Pennsylvania
Chapter 89

Barbara G. Wells, PharmD, FCCP, BCPP
Dean and Professor, Executive Director of the Research Institute of Pharmaceutical Sciences, School of Pharmacy, The University of Mississippi, Oxford, Mississippi
Chapters 77 and 80

Professor, Department of Medical Microbiology/Infectious Diseases, Faculty of Medicine, University of Manitoba, Winnipeg, Canada and Research Director-Canadian Antimicrobial Resistance Alliance (CARA) Winnipeg, Canada
Chapter 117

FOREWORD

The saying that "timing is everything" aptly describes the circumstances surrounding medication use in health care as this edition of *Pharmacotherapy: A Pathophysiologic Approach* goes to print. The U.S. Congress passed hallmark health reform legislation in March 2010 to expand access to health coverage, including pharmaceuticals and medication therapy management services, to millions of Americans. At the same time, many private sector efforts to make care safer and more affordable are moving forward. Massive movement is under way to enhance access to and coordinate electronic health records in health delivery in and between hospitals, physicians' offices and pharmacies.

What does this mean with respect to medication use? Perhaps the Patient-Centered Primary Care Collaborative[1] says it best.

> *Now is an important time in health care. Medications hold the promise to significantly improve the health of all Americans by effectively preventing and controlling many diseases, but they have fallen far short of this goal. Our current health care system rewards splintered, episodic care, which cripples our primary care system and silos medication use and costs from medical care and costs. As we truly coordinate care, we must also deliver on the promise of modern medications to prevent and control disease by directly linking their use to clinical goals and outcomes in a patient-centered fashion in a primary care team-based approach. Only with appropriate and optimal medication use will we see real quality of care improve and health care costs decrease in the patient-centered medical home (PCMH). Adherence to medications and recommended therapies is optimized when patients have a thorough understanding of all of their medications, including over-the-counter drugs, and how they impact their health when incentives are fairly aligned. Whole-person, patient-centered care—considering the mental and physical aspects of health—can be advanced by fully integrated care that includes clinically linked, comprehensive medication management.*

When the first edition of *Pharmacotherapy: A Pathophysiologic Approach* was published in 1988 the role of the clinical pharmacist was in the midst of its evolution and most who were prepared for advanced clinical roles utilized their skills and expertise in acute care settings. US colleges and schools of pharmacy only graduated about 1,000 PharmD graduates annually and debates were still raging about whether the accreditation standards for pharmacy education should change to make the Doctor of Pharmacy degree the entry level for licensure and practice. With the exception of a few key products for distinct diagnoses, medications were not a covered benefit for Medicare beneficiaries. Prescriptions were an optional benefit for state Medicaid programs. The federal government had little 'skin in the game' so to speak with respect to medications and their proper use and federal health policy makers devoted very little time to the pharmacotherapeutic elements of public or private sector health programs.

For so long pharmacy leaders seemed to be lone rangers when it came to identifying unmet needs for patient care related to the proactive management of patients' drug regimens. Justification for introducing clinical pharmacy services into hospitals and health systems, clinics, and other environments seemed to have to be made one unit, or one physician, or one chief financial officer at a time. For patients it would seem that the prevailing attitude was "if the FDA says this drug is approved and my physician prescribes it, it must be safe to take; and why would I need a pharmacist's services anyway?"

A glance back at the table of contents of the first edition of *Pharmacotherapy: A Pathophysiologic Approach* in comparison to the contents of the 8th edition is also revealing. With credit to the editors, the basic organizational structure of this world renowned text remains consistent. The first edition provided 111 chapters of essential information on pharmacotherapy for pharmacists and others who needed an essential reference on the pathophysiology and management of this array of diseases. The 8th edition has 154 chapters, almost a 50 percent increase in the coverage of specific conditions or areas of focus. This says nothing of the expansion of the depth of material in a given chapter.

It is also of interest to observe the transformation since 1988 of material the editors consider to be the "Foundational Issues" contained in Section 1 of the text. While important chapters such as geriatrics, pediatrics and pharmacokinetics remain at the core of the foundational pharmacotherapeutic content, these are accompanied by new chapters, including pharmacoeconomics and health outcomes, medication safety, health literacy and cultural competency. Biological, chemical and radiological terrorism also now appear in Section 1.

These simple but striking examples reveal the complexity of these times in health care and in pharmacy practice. As noted in the PCPCC treatise on MTM, "Medications hold the promise to significantly improve the health of all Americans by effectively preventing and controlling many diseases, but they have fallen far short of this goal." It is the growing recognition by health policy experts, health care delivery system leaders, patient safety advocates and others that a laisee faire approach to medication management is insufficient to advance contemporary care models.

As we enter the second decade of the 21st century a new recognition is dawning. Medication use is central to high quality, safe and effective patient care. This is true in prevention, acute care and chronic disease management. To use a term from the writing of Donald M. Berwick, MD, recently named the Administrator of the Centers for Medicare and Medicaid Services, medication management might well be an "integrator" in health care.[2] An integrator in Berwick's analysis enters a partnership with

individuals and families, redesigns primary care, addresses population health management, financial management and macro system integration.

Well designed programs of pharmacotherapy management touch on each of these elements and call upon the knowledge, skills and abilities of medication use specialists. Colleges and schools of pharmacy and their faculty members offer curricula that provide the foundational abilities for pharmacists to enter practice across all settings of care and manage patients' drug therapy. Often with post-graduate training, pharmacists apply their unique insights into the care of patients with the broad array of conditions described in this text and especially those that are most challenging. That may be a patient with a newly transplanted and life-saving organ or an elderly woman with six chronic ailments and a pharmacotherapy regimen of 10 to 12 prescriptions, over the counter and nutritional products. Longitudinal care management for individuals with chronic conditions such as diabetes, asthma, congestive heart failure and depression that respond to well-designed pharmacotherapeutic regimens also shows consistent improvement when a medication use specialist is directly involved in the patient's care.

There are numerous stakeholders in the realm of effective medication use and the management of complex medical conditions. Fortunately, *Pharmacotherapy: A Pathophysiologic Approach* continues the fine tradition of organizing essential information in a systematic fashion to guide the evaluation, individualization, and rationalization of drug therapy for the entire array of patients and their medical conditions. The depth and breadth of information contained in this text long ago surpassed the ability of any one clinician to command it entirely. We have therefore seen specialists emerge in virtually each area while many clinicians continue to work to coordinate and optimize care plans that are more routine but require continuous patient education and monitoring. The time is now to make good on the promise of relief of suffering and compassionate care that can be achieved when medications are used properly and managed effectively. The 8th edition of *Pharmacotherapy: A Pathophysiologic Approach* will help assure the promise is realized.

FOREWORD TO THE FIRST EDITION

Evidence of the maturity of a profession is not unlike that characterizing the maturity of an individual; a child's utterances and behavior typically reveal an unrealized potential for attainment, eventually, of those attributes characteristic of an appropriately confident, independently competent, socially responsible, sensitive, and productive member of society.

Within a period of perhaps 15 or 20 years, we have witnessed a profound maturation within the profession of pharmacy. The utterances of the profession, as projected in its literature, have evolved from mostly self-centered and self-serving issues of trade protection to a composite of expressed professional interests that prominently include responsible explorations of scientific/technological questions and ethical issues that promote the best interests of the clientele served by the profession. With the publication of *Pharmacotherapy: A Pathophysiologic Approach,* pharmacy's utterances bespeak a matured practitioner who is able to call upon unique knowledge and skills so as to function as an appropriately confident, independently competent pharmacotherapeutics expert.

In 1987, the Board of Pharmaceutical Specialties (BPS), in denying the petition filed by the American College of Clinical Pharmacy (ACCP) to recognize "clinical pharmacy" as a specialty, conceded nonetheless that the petitioning party had documented in its petition a specialist who does in fact exist within the practice of pharmacy and whose expertise clearly can be extricated from the performance characteristics of those in general practice. A refiled petition from ACCP requests recognition of "pharmacotherapy" as a Specialty Area of Pharmacy Practice. While the BPS had issued no decision when this book went to press, it is difficult to comprehend the basis for a rejection of the second petition.

Within this book one will find the scientific foundation for the essential knowledge required of one who may aspire to specialty practice as a pharmacotherapist. As is the case with any such publication, its usefulness to the practitioner or the future practitioner is limited to providing such a foundation. To be socially and professionally responsible in practice, the pharmacotherapist's foundation must be continually supplemented and complemented by the flow of information appearing in the primary literature. Of course this is not unique to the general or specialty practice of pharmacy; it is essential to the fulfillment of obligations to clients in any occupation operating under the code of professional ethics.

Because of the growing complexity of pharmacotherapeutic agents, their dosing regimens, and techniques for delivery, pharmacy is obligated to produce, recognize, and remunerate specialty practitioners who can fulfill the profession's responsibilities to society for service expertise where the competence required in a particular case exceeds that of the general practitioner. It simply is a component of our covenant with society and is as important as any other facet of that relationship existing between a profession and those it serves.

The recognition by BPS of pharmacotherapy as an area of specialty practice in pharmacy will serve as an important statement by the profession that we have matured sufficiently to be competent and willing to take unprecedented responsibilities in the collaborative, pharmacotherapeutic management of patient-specific problems. It commits pharmacy to an intention that will not be uniformly or rapidly accepted within the established health care community. Nonetheless, this formal action places us on the road to an avowed goal, and acceptance will be gained as the pharmacotherapists proliferate and establish their importance in the provision of optimal, cost-effective drug therapy.

Suspecting that other professions in other times must have faced similar quests for recognition of their unique knowledge and skills I once searched the literature for an example that might parallel pharmacy's modern-day aspirations. Writing in the *Philadelphia Medical Journal,* May 27, 1899, D. H. Galloway, MD, reflected on the need for specialty training and practice in a field of medicine lacking such expertise at that time. In an article entitled "The Anesthetizer as a Speciality," Galloway commented:

> *The anesthetizer will have to make his own place in medicine: the profession will not make a place for him, and not until he has demonstrated the value of his services will it concede him the position which the importance of his duties entitles him to occupy. He will be obliged to define his own rights, duties and privileges, and he must not expect that his own estimate of the importance of his position will be conceded without opposition. There are many surgeons who are unwilling to share either the credit or the emoluments of their work with anyone, and their opposition will be overcome only when they are shown that the importance of their work will not be lessened, but enhanced, by the increased safety and dispatch with which operations may be done. . . .*

It has been my experience that, given the opportunity for one-on-one, collaborative practice with physicians and other health professionals, pharmacy practitioners who have been educated and trained to perform at the level of pharmacotherapeutics specialists almost invariably have convinced the former that "the importance of their work will not be lessened, but enhanced, by the increased safety and dispatch with which" individualized problems of drug therapy could be managed in collaboration with clinical pharmacy practitioners.

It is fortuitous—the coinciding of the release of *Pharmacotherapy: A Pathophysiologic Approach* with ACCP's petitioning of BPS for recognition of the pharmacotherapy specialist. The utterances of a maturing profession as revealed in the contents of this book, and the intraprofessional recognition and acceptance of a higher level of responsibility in the safe, effective, and economical use of drugs and drug products, bode well for the future of the profession and for the improvement of patient care with drugs.

PREFACE

Health care has entered an era of change more dramatic than any in the last few decades. While issues related to health care access and coverage, including payment for care, dominate the media, health care providers are challenged daily to meet the needs and demands for wellness services, primary care and chronic disease management, end-of-life care, and specialty care. Effective health care practitioners now must be able to manage the economic burdens of care, including psychosocial dimensions, and apply the latest advances in the health sciences. This is true just as much with the management of patient-centered pharmacotherapy as with any other aspect of health care. To remain relevant and effective, the pharmacotherapist must maintain a commitment to life-long learning in the interest of caring for patients.

The 8th edition of *Pharmacotherapy: A Pathophysiologic Approach* has six new chapters. The first section of the book includes new chapters on Palliative Care, Health Literacy, Cultural Competency, and Medication Safety. A new chapter on Celiac Disease addresses a condition that is now recognized as affecting as many as 1 of every 300 people in the United States. There is also a new chapter on Renal Cell Carcinoma, and the chapters on acutely decompensated heart failure and cystic fibrosis have been completely rewritten. Most importantly, each chapter of the book has been updated to reflect the latest in evidence-based information and recommendations. We have done our best to balance the need for accurate, thorough, and unbiased information about the treatment of diseases with the practical limitations of paper books.

With each edition, the editors recommit to our founding precepts:

- Advance the quality of patient care through evidence-based medication therapy management based on sound pharmacotherapeutic principles.
- Enhance the health of our communities by incorporating contemporary health promotion and disease-prevention strategies in our practice environments.
- Motivate young practitioners to enhance the breadth, depth, and quality of care they provide to their patients.
- Challenge established pharmacists and other primary-care providers to learn new concepts and refine their understanding of the pathophysiologic tenets that undergird the development of individualized therapeutic regimens.
- Present the pharmacy and health care communities with innovative patient assessment, triage, and pharmacotherapy management skills.

The eighth edition continues the emphasis on evidenced-based pharmacotherapy. Most of the disease-oriented chapters have incorporated updated evidence-based treatment guidelines that include, when available, ratings of the level of evidence to support the key therapeutic approaches. Also, in this edition key features have been retained, including:

- Key concepts listed at the beginning of each chapter are identified in the text with numbered icons so that the reader can easily jump to the material of interest.
- The most common signs and symptoms of diseases are presented in highlighted *Clinical Presentation* tables in disease-specific chapters.
- Clinical controversies in treatment or patient management are highlighted to assure that the reader is aware of these issues and how practitioners are responding to them.
- Each chapter has approximately 100 of the most important and current references relevant to each disease, with most published since 2005.
- The diagnostic flow diagrams, treatment algorithms, dosing guideline recommendations, and monitoring approaches that were present in the last edition have been refined.

We have made a special effort with this edition to have authors summarize concepts more succinctly or use tables to present details more concisely. This process continued as the book entered production, and even during the review of final proofs, we continued to make changes to ensure that this book is as current and complete as is possible.

To make room for new chapters and stay with a single volume of *Pharmacotherapy*, 21 chapters of this edition are being published in our Pharmacotherapy Online Learning Center, accessible at www.pharmacotherapyonline.com or http://highered.mcgraw-hill.com/sites/0071416137/information_center_view0/. The chapters chosen for Web publication include those of specialized application that may be predominantly used by practitioners, rather than being core elements of the pharmacotherapy sequences at colleges of pharmacy. The online chapters include those describing details about the diagnosis of organ system diseases. In addition, 14 chapters printed in the book also appear online to enhance student and instructor access.

As the world increasingly relies on electronic means of communication, we are committed to keeping *Pharmacotherapy* and its companion works, *Pharmacotherapy Casebook: A Patient-Focused Approach and Pharmacotherapy Handbook,* integral components of clinicians' toolboxes. The Online Learning Center continues to provide unique features designed to benefit students, practitioners, and faculty around the world. The site includes learning objectives and self-assessment questions for each chapter, and the full text of this book is now available on the publisher's AccessPharmacy site (www.accesspharmacy.com). In AccessPharmacy, each section of the book also has updates published periodically and editorial comment about the relevance of more recent information.

In closing, we acknowledge the many hours that *Pharmacotherapy's* more than 300 authors contributed to this labor of love. Without their devotion to the cause of improved pharmacotherapy and dedication in maintaining the accuracy, clarity, and relevance of their chapters, this text would unquestionably not be possible. In addition, we thank Michael Weitz, Karen Edmonson, and James Shanahan and their colleagues at McGraw-Hill for their consistent support of the *Pharmacotherapy* family of resources, insights into trends in publishing and higher education, and the critical attention to detail so necessary in pharmacotherapy.

The Editors
March 2011

FOUNDATION ISSUES

CHAPTER 1

Pharmacoeconomics: Principles, Methods, and Applications

LISA SANCHEZ TRASK

KEY CONCEPTS

1. Pharmacoeconomics identifies, measures, and compares the costs and consequences of drug therapy to healthcare systems and society.
2. The perspective of a pharmacoeconomic evaluation is paramount because the study results will be highly dependent on the perspective selected.
3. Healthcare costs can be categorized as direct medical, direct nonmedical, indirect nonmedical, intangible, opportunity, and incremental costs.
4. Economic, humanistic, and clinical outcomes should be considered and valued using pharmacoeconomic methods, to inform local decision making whenever possible.
5. To compare various healthcare choices, economic valuation methods are used, including cost-minimization, cost-benefit, cost-effectiveness, and cost-utility analyses. These methods all provide the means to compare competing treatment options and are similar in the way they measure costs (dollar units). They differ, however, in their measurement of outcomes and expression of results.
6. In today's healthcare settings, pharmacoeconomic methods can be applied for effective formulary management, individual patient treatment, medication policy determination, and resource allocation.
7. When evaluating published pharmacoeconomic studies, the following factors should be considered: study objective, study perspective, pharmacoeconomic method, study design, choice of interventions, costs and consequences, discounting, study results, sensitivity analysis, study conclusions, and sponsorship.
8. Both the use of economic models and conducting pharmacoeconomic analyses on a local level can be useful and relevant sources of pharmacoeconomic data when rigorous methods are employed, as outlined in this chapter.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

Today's cost-sensitive healthcare environment has created a competitive and challenging workplace for clinicians. Competition for diminishing resources has necessitated that the appraisal of healthcare goods and services extends beyond evaluations of safety and efficacy and considers the economic impact of these goods and services on the cost of healthcare. A challenge for healthcare professionals is to provide quality patient care while assuring an efficient use of resources.

Defining the *value* of medicine is a common thread that unites today's healthcare practitioners. With serious concerns about rising medication costs and consistent pressure to decrease pharmacy expenditures and budgets, clinicians/prescribers, pharmacists, and other healthcare professionals must answer the question, "What is the value of the pharmaceutical goods and services I provide?" *Pharmacoeconomics*, or the discipline of placing a value on drug therapy,[1] has evolved to answer that question.

Challenged to provide high-quality patient care in the least expensive way, clinicians have developed strategies aimed at containing costs. However, most of these strategies focus solely on determining the least expensive alternative rather than the alternative that represents the best value for the money. The "cheapest" alternative—with respect to drug acquisition cost—is not always the best value for patients, departments, institutions, and healthcare systems.

Quality patient care must not be compromised while attempting to contain costs. The products and services delivered by today's healthcare professionals should demonstrate *pharmacoeconomic value*—that is, a balance of economic, humanistic, *and* clinical outcomes. Pharmacoeconomics can provide the systematic means for this quantification. This chapter discusses the principles and methods of pharmacoeconomics and how they can be applied to clinical pharmacy practice, and thereby how they can assist in the valuation of pharmacotherapy and other modalities of treatment in clinical practice.

CHAPTER 2

Health Outcomes and Health-Related Quality of Life

STEPHEN JOEL COONS

KEY CONCEPTS

1. The evaluation of healthcare is increasingly focused on the assessment of the *outcomes* of medical interventions.
2. An essential patient-reported outcome is self-assessed function and well-being, or health-related quality of life (HRQOL).
3. In certain chronic conditions, HRQOL may be the most important health outcome to consider in assessing treatment impact.
4. Information about the impact of pharmacotherapy on HRQOL can provide additional data for making decisions regarding medication use.
5. HRQOL instruments can be categorized as generic/general or targeted/specific.
6. In HRQOL research, the quality of the data collection tool is the major determinant of the overall quality of the results.

The medical care marketplace in the United States continues to experience change in both the financing and delivery of care.[1] This change is evidenced by a variety of developments, including an increase in investor-owned organizations, consolidation through mergers and acquisitions, increasingly sophisticated clinical and administrative information systems, and new financing and organizational structures. In this dynamic and increasingly complex environment, there is a concern that healthcare quality is being compromised in the push to contain costs.[2] 1 As a consequence, there has been a growing movement to focus the evaluation of healthcare on the assessment of the end results, or *outcomes,* associated with medical care delivery systems as well as specific medical interventions. The primary objective of this effort is to maximize the net health benefit derived from the use of finite healthcare resources.[3] However, there is a profound lack of critical information as to what value is received for the tremendous amount of resources expended on medical care.[4] This lack of critical information as to the outcomes produced is an obstacle to optimal healthcare decision making at all levels.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

HEALTH OUTCOMES

Although the implicit objective of medical care is to improve health outcomes, until relatively recently, little attention was paid to the explicit measurement of them. An outcome is one of the three components of the conceptual framework articulated by Donabedian for assessing and ensuring the quality of healthcare: *structure, process,* and *outcome.*[4] For far too long, the approach to evaluating healthcare had emphasized the structure and processes involved in medical care delivery rather than the outcomes. However, healthcare regulators, payers, providers, manufacturers, and patients are placing increasing emphasis on the outcomes that medical care products and services produce.[5] As stated by Ellwood, outcomes research is "designed to help patients, payers, and providers make rational medical care choices based on better insight into the effect of these choices on the patient's life."[6]

TYPES OF OUTCOMES

The types of outcomes that result from medical care interventions can be described in a number of ways. One classic list, called the *five D's*—death, disease, disability, discomfort, and dissatisfaction—captures a limited range of outcomes for use in assessing the quality of medical care.[7] The *five D's* do not reflect any positive health outcomes and, as a result, have little value in contemporary outcomes research. A more comprehensive conceptual framework, the ECHO model, places outcomes into three categories: *e*conomic, *c*linical, and *h*umanistic *o*utcomes.[8] As described by Kozma et al.,[8] *economic outcomes* are the direct, indirect, and intangible costs compared with the consequences of a medical intervention. *Clinical outcomes* are the medical events that occur as a result of the condition and/or its treatment. 2 *Humanistic outcomes,* which now are more commonly called *patient-reported outcomes,*[9] are the consequences of the disease and/or its treatment as perceived and reported by the patient.

CHAPTER 3

Health Literacy and Medication Use

ORALIA V. BAZALDUA AND SUNIL KRIPALANI

KEY CONCEPTS

1. Limited health literacy is common and must be considered when providing medication management services.
2. Some groups of people are at higher risk for having limited literacy skills, but in general, you cannot tell by looking.
3. Patients with limited health literacy are more likely to misunderstand medication instructions and have difficulty demonstrating the correct dosing regimen.
4. Limited health literacy is associated with increased healthcare costs and worse health outcomes, including increased mortality.
5. Despite numerous efforts to improve safe medication practices, current strategies have been inadequate, and this may have a larger impact in patients with limited literacy.
6. Most printed materials are written at higher comprehension levels than most adults can read.
7. Health literacy experts are advocating standardization of prescription medication labels to minimize patient confusion.
8. Several instruments exist to measure health literacy, but some experts advocate "universal precautions" under which all patients are assumed to benefit from plain language and clear communication.
9. Obtaining a complete medication history and providing medication counseling are vital components in the medication management of patients with limited health literacy.

Every day, thousands of patients are not taking their medications correctly. Some take too much. Others take too little. Some use a tablespoon instead of a teaspoon. Parents pour an oral antibiotic suspension in their child's ear instead of giving it by mouth because it was prescribed for an ear infection. Others are in the emergency department because they did not know how to use their asthma inhaler. It is not a deliberate revolt against the doctor's orders but rather a likely and an unfortunate result of a hidden risk factor—limited health literacy.

1 *Literacy*, at the basic level, is simply the ability to read and write. When these skills are applied to a health context, it is called *health literacy*, but health literacy is more than just reading and writing. *Health literacy*, as defined by the Institute of Medicine (IOM), is "the degree to which individuals have the capacity to obtain, process and understand basic health information and services needed to make appropriate health decisions." A growing body of evidence associates low health literacy with less understanding, worse outcomes, and increased cost, and these poor outcomes have led this topic to receive national attention. Health literacy has been made "a priority area for national action" by the IOM[1] and Healthy People 2010.[2] Likewise, the Agency for Healthcare Research and Quality (AHRQ) and the National Institutes of Health (NIH) have dedicated a website to this topic and have provided funding to support studies and interventions that are specifically relevant to health literacy.[3,4] Indeed, health literacy should be a national priority for the medical community as its consequences are far-reaching and crosscutting.

CHAPTER 4

Cultural Competency

JERI J. SIAS, AMANDA M. LOYA, JOSÉ O. RIVERA, ARTHUR A. ISLAS, AND ULYSSES J. URQUIDI

KEY CONCEPTS

1. Healthcare providers should strive toward cultural competency to improve care to patients and communities from diverse cultures and backgrounds.
2. Changes in demographics in the United States, health disparities, and patient safety are among the reasons that cultural competency needs to be emphasized in healthcare.
3. Stages of cultural competency include cultural destructiveness, incapacity, blindness, pre-competency, competency, and proficiency.
4. Legal and regulatory issues surrounding cultural competency include understanding and interpreting accreditation standards for healthcare organizations and Title VI of the Civil Rights Act.
5. Patients may enter the healthcare setting with a different explanation of their illnesses than found in the Western biomedical model.
6. Factors that can influence cultural values and beliefs toward healthcare include racial, ethnic, age, gender, sexual orientation, as well as religious backgrounds.
7. Developing communication skills to interact with diverse populations includes recognizing personal styles of communication as well as barriers to patient understanding.
8. Linguistic competency encompasses understanding issues related to working with patients with limited English proficiency and/or hearing impairments, such as learning basic terms and greetings, working with an interpreter or language-assistance lines, using non-English patient education/materials.
9. Skills for working with patients from diverse cultures include being able to listen to the patient's perception of health, acknowledge difference, be respectful, and negotiate treatment options.
10. Before they can understand other cultures, practitioners should understand personal and organizational values and beliefs.

CULTURE, COMMUNITY, AND SOCIAL DETERMINANTS OF HEALTH

Culture defines us.[1] Although our genetic make-up influences who we are, social determinants of health are also of great influence (Fig. 4–1). For example, our socioeconomic status, our race and ethnicity, our gender, our age, and our communities (environments), as part of our cultures, shape us.[2] Consider the following brief descriptions of three individuals. Patient 1 is a 30-year-old bilingual Vietnamese American Buddhist woman living on the West Coast whose family immigrated to the United States 5 years ago. Patient 2 is a 30-year-old African American Muslim upper-middle class man living in a major city in the Great Lakes region of the United States. Patient 3 is a 30-year-old trilingual European American Protestant middle class man living on the East Coast. Can healthcare professionals assume that because these patients are the same age that their healthcare beliefs and values as well as their approach to healthcare are the same? While each of the patients described above will have a unique health situation, their cultural backgrounds have likely influenced their health beliefs and behaviors.

CHAPTER 5

Principles and Practices of Medication Safety

SCOTT M. MARK, JEFFREY D. LITTLE, SARAH E. ADKINS, AND ROBERT J. WEBER

KEY CONCEPTS

1. Medication errors (MEs) are defined as *any* mistake at *any* stage of the medication use process; adverse drug events (ADEs) are the result of an injury to a drug-related intervention, regardless of whether an error has occurred.
2. All MEs can be prevented, while ADEs can be categorized as preventable, nonpreventable, or potential.
3. MEs occur at an alarmingly high rate, and some MEs and ADEs have fatal outcomes for patients.
4. MEs can result from any step of the medication-use process: selection and procurement, storage, ordering and transcribing, preparing and dispensing, administration, or monitoring.
5. MEs can be prevented by determining the actual and potential root causes in the medication-use system and correcting them.
6. Quality improvement methods that prevent MEs and thereby minimize ADEs include identifying the ME/ADE, understanding the reasons for the ME/ADE, designing and implementing a change to prevent an ADE/ME, and checking the outcome of that change.
7. A "Just Culture" of medication safety cultivates trust in the workplace that makes personnel feel comfortable sharing safety information (e.g., unsafe situations) and assuming personal responsibility for complying with safe medication practices.

Medical mistakes that cause harm have a devastating effect on patients in the healthcare system. In 1991, the Harvard Medical Practice Study showed that a significant number of people are victims of MEs. This landmark study reviewing safety in the state of New York showed that almost four percent of patients experienced an iatrogenic injury (one caused by healthcare practices or procedures), prolonging their hospital stays.[1] Importantly, nearly 14% of those mistakes were fatal. Examples of mistakes noted in the Harvard study included renal failure from angiographic dye, colon laceration during a therapeutic abortion, and a missed diagnosis of colon cancer. Drug complications were the most common type of outcome attributed to negligence, accounting for 19% of these preventable adverse events.[1]

CHAPTER 6

Evidence-Based Medicine

ELAINE CHIQUETTE AND L. MICHAEL POSEY

KEY CONCEPTS

1. The best current evidence integrated into clinical expertise ensures optimal care for patients.
2. The four steps in the process of applying evidence-based medicine (EBM) in practice are (a) formulate a clear question from a patient's problem, (b) identify relevant information, (c) critically appraise available evidence, and (d) implement the findings in clinical practice.
3. The decision to implement results of a specific study, conclusions of a review article, or another piece of evidence in clinical practice depends on the quality (i.e., internal validity) of the evidence, its clinical importance, whether benefits outweigh risks and costs, and its relevance in the clinical setting and patient's circumstances.
4. EBM strategies help keep one current in their field of expertise.
5. EBM is realistic.

In the information age, clinicians are presented with a daunting number of diseases and possible treatments to consider as they care for patients each day. As knowledge increases and technology for accessing information becomes widely available, healthcare professionals are expected to stay current in their fields of expertise and to remain competent throughout their careers. In addition, the number of information sources for the typical practitioner has ballooned, and clinicians must sort out information from many sources, including college courses and continuing education (e.g., seminars and journals), pharmaceutical representatives, and colleagues, as well as guidelines from committees of healthcare facilities, government agencies, and expert committees and organizations.

1 How does the healthcare professional find valid information from such a cacophony? Increasingly, clinicians are turning to the principles of EBM to identify the best course of action for each patient. EBM strategies help healthcare professionals to ferret out these gold nuggets, enabling them to integrate the best current evidence into their pharmacotherapeutic decision making. These strategies can help physicians, pharmacists, and other healthcare professionals to distinguish reliably beneficial pharmacotherapies from those that are ineffective or harmful. In addition, EBM approaches can be applied to keep up-to-date and to make an overwhelming task seem more manageable.

CHAPTER 7

Documentation of Pharmacy Services

GEORGE E. MACKINNON III AND NEIL J. MACKINNON

KEY CONCEPTS

1. Documentation of pharmacists' interventions, their actions and impact on patient outcomes is central to the process of pharmaceutical care.
2. Unless pharmacists in all practice settings document their activities and communicate with other healthcare professionals, they may not be considered an essential and integral part of the healthcare team.
3. Manual systems of documentation for pharmacists have been described in detail, but increasingly electronic systems are used to facilitate integration with other clinicians, payer records, and healthcare systems.
4. Integrated electronic information systems can facilitate provision of seamless care as patients move among ambulatory, acute, and long-term care settings.
5. Medication reconciliation, a process of ensuring documentation of the patient's correct medication profile, has become a central part of patient safety activities in recent years.
6. Systems of pharmacy documentation are becoming increasingly important models in the United States as the Medicare Part D Prescription Drug Plan and accompanying medication therapy management services are further implemented.
7. Electronic medical records and prescribing systems have several advantages over manual systems that will facilitate access by community pharmacists and their participation as fully participating and acknowledged members of the healthcare team.

As the opportunities to become more patient-focused increase and market pressures exert increased accountability for pharmacists' actions, the importance of documenting pharmacists' professional activities related to patient care will become paramount in the years to come. Processes to document the clinical activities and therapeutic interventions of pharmacists have been described extensively in the pharmacy literature, yet universal adoption of documentation throughout pharmacy practice remains inconsistent, incomplete, and misunderstood.

1 Documentation is central to the provision of patient-centered care/pharmaceutical care.[1] Pharmaceutical care is provided through a "system" in which feedback loops are established for monitoring purposes. This has advantages compared with the traditional medication-use process because the system enhances communication among members of the healthcare team and the patient. Pharmaceutical care requires responsibility by the provider to identify drug-related problems (DRPs), provide a therapeutic monitoring plan, and ensure that patients receive the most appropriate medicines and ultimately achieve their desired level of health-related quality of life (HRQOL).

To provide pharmaceutical care, the pharmacist, patient, and other providers enter a covenantal relationship that is considered to be mutually beneficial to all parties. The patient grants the pharmacist the opportunity to provide care, and the pharmacist, in turn, must accept this and the responsibility it entails. Documentation enables the pharmaceutical care model of pharmacy practice to be maximized and communicated to vested parties. Communication among sites of patient care must be accurate and timely to facilitate pharmaceutical care. As discussed by Hepler,[1] documentation supports care that is coordinated, efficient, and cooperative.

CHAPTER 8

Clinical Pharmacokinetics and Pharmacodynamics

LARRY A. BAUER

KEY CONCEPTS

1. Clinical pharmacokinetics is the discipline that describes the absorption, distribution, metabolism, and elimination of drugs in patients requiring drug therapy.
2. Clearance is the most important pharmacokinetic parameter because it determines the steady-state concentration for a given dosage rate. Physiologically, clearance is determined by blood flow to the organ that metabolizes or eliminates the drug and the efficiency of the organ in extracting the drug from the bloodstream.
3. The volume of distribution is a proportionality constant that relates the amount of drug in the body to the serum concentration. The volume of distribution is used to calculate the loading dose of a drug that will immediately achieve a desired steady-state concentration. The value of the volume of distribution is determined by the physiologic volume of blood and tissues and how the drug binds in blood and tissues.
4. Half-life is the time required for serum concentrations to decrease by one-half after absorption and distribution are complete. It is important because it determines the time required to reach steady state and the dosage interval. Half-life is a dependent kinetic variable because its value depends on the values of clearance and volume of distribution.
5. The fraction of drug absorbed into the systemic circulation after extravascular administration is defined as its bioavailability.
6. Most drugs follow linear pharmacokinetics, whereby steady-state serum drug concentrations change proportionally with long-term daily dosing.
7. Some drugs do not follow the rules of linear pharmacokinetics. Instead of steady-state drug concentration changing proportionally with the dose, serum concentration changes more or less than expected. These drugs follow nonlinear pharmacokinetics.
8. Pharmacokinetic models are useful to describe data sets, to predict serum concentrations after several doses or different routes of administration, and to calculate pharmacokinetic constants such as clearance, volume of distribution, and half-life. The simplest case uses a single compartment to represent the entire body.
9. Factors to be taken into consideration when deciding on the best drug dose for a patient include age, gender, weight, ethnic background, other concurrent disease states, and other drug therapy.
10. Cytochrome P450 is a generic name for the group of enzymes that are responsible for most drug metabolism oxidation reactions. Several P450 isozymes have been identified, including CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

This page intentionally left blank

CHAPTER 9

Pharmacogenetics

LARISA H. CAVALLARI AND Y. W. FRANCIS LAM

KEY CONCEPTS

1. Genetic variation contributes to pharmacokinetic and pharmacodynamic drug properties.
2. Genetic variation occurs for drug metabolism, drug transporter, and drug target proteins, as well as disease-associated proteins.
3. Single-nucleotide polymorphisms are the most common gene variations associated with drug response.
4. Genetic polymorphisms may influence drug efficacy or toxicity.
5. Pharmacogenetics is the study of the impact of genetic polymorphisms on drug response.
6. The goals of pharmacogenetics are to optimize drug efficacy and limit drug toxicity based on an individual's DNA.
7. Gene therapy aims to cure disease caused by genetic defects by changing gene expression.
8. Inadequate gene delivery and expression and serious adverse effects are obstacles to successful gene therapy.

Great variability exists among individuals in response to drug therapy, and it is difficult to predict how effective or safe a medication will be for a particular patient. For example, when treating a patient with hypertension, it may be necessary to try several agents or a combination of agents before achieving adequate blood pressure control with acceptable tolerability. A number of clinical factors are known to influence drug response, including age, body size, renal and hepatic function, and concomitant drug use. However, considering these factors alone is often insufficient in predicting the likelihood of drug efficacy or safety for a given patient. For instance, identical antihypertensive therapy in two patients of similar age, sex, race, and with similar medical histories and concomitant drug therapy may produce inadequate blood pressure reduction in one patient and symptomatic hypotension in the other.

1 2 The observed interpatient variability in drug response may result largely from genetically determined differences in drug metabolism, drug distribution, and drug target proteins. The influence of heredity on drug response was demonstrated as early as 1956 with the discovery that an inherited deficiency of glucose-6-phosphate dehydrogenase (G6PD) was responsible for hemolytic reactions to the antimalarial drug primaquine.[1] Variations in genes encoding cytochrome P450 (CYP) and other drug-metabolizing enzymes are now well recognized as causes of interindividual differences in plasma concentrations of certain drugs. These variations may have serious implications for narrow-therapeutic-index drugs such as warfarin, phenytoin, and mercaptopurine.[2–4] Other variations associated with drug response occur in genes for drug transporters such as P-glycoprotein and drug targets such as receptors, enzymes, and proteins involved in intracellular signal transduction. Genetic variations for drug-metabolizing enzymes and drug transporter proteins may influence drug disposition, thus altering pharmacokinetic drug properties. Drug target genes may alter pharmacodynamic mechanisms by affecting sensitivity to a drug at its target site. Finally, genes associated with disease severity have been correlated with drug efficacy despite having no direct effect on pharmacokinetic or pharmacodynamic mechanisms.

This page intentionally left blank

CHAPTER 10

Pediatrics

MILAP C. NAHATA AND CAROL TAKETOMO

KEY CONCEPTS

1. Children are not just "little adults," and lack of data on important pharmacokinetic and pharmacodynamic differences has led to several disastrous situations in pediatric care.
2. Variations in absorption of medications from the gastrointestinal tract, intramuscular injection sites, and skin are important in pediatric patients, especially in premature and other newborn infants.
3. The rate and extent of organ function development and the distribution, metabolism, and elimination of drugs differ not only between pediatric versus adult patients but also among pediatric age groups.
4. The effectiveness and safety of drugs may vary among age groups and from one drug to another in pediatric versus adult patients.
5. Concomitant diseases may influence dosage requirements to achieve a targeted effect for a specific disease in children.
6. Use of weight-based dosing of medications for obese children may result in suboptimal drug therapy.
7. The myth that neonates and young infants do not experience pain has led to inadequate pain management in this pediatric population.
8. Special methods of drug administration are needed for infants and young children.
9. Many medicines needed for pediatric patients are not available in appropriate dosage forms; thus, the dosage forms of drugs marketed for adults may require modification for use in infants and children, necessitating assurance of potency and safety of drug use.
10. The pediatric medication-use process is complex and error-prone because of the multiple steps required in calculating, verifying, preparing, and administering doses.

Remarkable progress has been made in the clinical management of disease in pediatric patients. This chapter highlights important principles of pediatric pharmacotherapy that must be considered when the diseases discussed in other chapters of this book occur in pediatric patients, defined as those younger than 18 years. Newborn infants born before 37 weeks of gestational age are termed *premature;* those between 1 day and 1 month of age are *neonates;* 1 month to 1 year are *infants;* 1 to 11 years are *children;* and 12 to 16 years are *adolescents.* This chapter covers notable examples of problems in pediatrics, pharmacokinetic differences in pediatric patients, drug efficacy and toxicity in this patient group, and various factors affecting pediatric pharmacotherapy. Specific examples of problems and special considerations in pediatric patients are cited to enhance understanding.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

CHAPTER 11

Geriatrics

EMILY R. HAJJAR, SHELLY L. GRAY, DAVID R.P. GUAY, CATHERINE I. STARNER, STEVEN M. HANDLER, AND JOSEPH T. HANLON

KEY CONCEPTS

1. The population of persons aged 65 years and older is increasing.
2. Age-related changes in physiology can affect the pharmacokinetics and pharmacodynamics of numerous drugs.
3. Improving and maintaining functional status is a cornerstone of care for older adults.
4. Drug-related problems in older adults are common and cause considerable morbidity.
5. Pharmacists can play a major role in optimizing drug therapy and preventing drug-related problems in older adults.

Pharmacotherapy for older adults can cure or palliate disease as well as enhance health-related quality of life (HRQOL). HRQOL considerations for older adults include focusing on improvements in physical functioning (e.g., activities of daily living), psychological functioning (e.g., cognition, depression), social functioning (e.g., social activities, support systems), and overall health (e.g., general health perception).[1] Despite the benefits of pharmacotherapy, HRQOL can be compromised by drug-related problems. The prevention of drug-related adverse consequences in older adults requires that health professionals become knowledgeable about a number of age-specific issues. To address these knowledge needs, this chapter discusses the epidemiology of aging; physiologic changes associated with aging, with emphasis on those changes that can affect the pharmacokinetics and pharmacodynamics of drugs; clinical conditions commonly seen in older adult patients; epidemiology of drug-related problems in older adults; and an approach to reducing drug-related problems through the provision of comprehensive geriatric assessment.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

This page intentionally left blank

CHAPTER 12

Palliative Care

JILL ASTOLFI

KEY CONCEPTS

1. The goal of palliative care is to improve overall quality of life for patients, caregivers, and families while managing both general and disease-specific symptoms each patient may experience.
2. Both palliative care and hospice use a team approach to address the total care of the patient and manage his or her symptoms.
3. Palliative care should be instituted at the time of diagnosis and carried through to a patient's death; it can and should be administered simultaneously while a patient is receiving curative or life-prolonging therapies.
4. It is important to address and manage each end-of-life symptom to improve the quality of life for the patient.
5. Patients may experience different pain syndromes at the end of life. Knowledge of pain classification is important and necessary to determine the appropriate medication treatment for each patient.
6. An interdisciplinary team approach is beneficial throughout the care of the patient. This is evident when addressing more psychologically based symptoms, such as delirium.
7. Various symptoms will develop as death approaches. Anticipation, preparation, and access to appropriate treatment measures are necessary for a peaceful death.

1 Approximately 2.4 million people die each year in the United States, most as a result of chronic illnesses.[1] For patients with advanced disease or life-limiting illness, access to appropriate symptom management is of great concern, as are access to social, psychological, and spiritual support. A field of medicine known as palliative care focuses on reducing suffering and improving the quality of life for patients, their families, and caregivers. The purpose of palliative care is symptom assessment, prevention, and management. In addition, palliative care establishes goals of care with each patient and caregiver and extends support to the patient, family, and caregivers while addressing the individual patient's needs across all models of patient care settings (i.e., hospital, home, nursing home, and hospice).[2] Palliative care teams depend on the expertise of healthcare professionals from various disciplines; this helps to address the complex needs of seriously ill patients and their families. Typical members of a palliative care team are physicians, nurses, and social workers, with additional support from pharmacy, chaplaincy, nutrition, and other disciplines as needed.

Pharmacists serve an integral role in palliative care and hospice teams. They often participate in interdisciplinary team meetings, while others are employed by home health and hospital agencies and provide consultative services to interdisciplinary teams. Other pharmacists may work for an in-house hospice pharmacy or be employed by specialized hospice pharmacies throughout the country. Pharmacists typically provide appropriate medication recommendations and education for both staff and patients on appropriate use of medications. Some pharmacists are allowed to alter or initiate medications and dosages within a confined algorithm. Others provide recommendations to nurses and physicians regarding the medication therapy.

Overall, pharmacists can improve patient outcomes and symptom management by providing cost-effective medication recommendations, reviewing medication profiles, decreasing or eliminating duplicative medications, recommending alternative medication dosage forms (i.e., compounded medications) when appropriate, monitoring medications for both effectiveness and side effects, and educating staff, patients, and family on appropriate use of medication.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

This page intentionally left blank

CHAPTER 13

Pharmacoepidemiology

ANDY STERGACHIS, THOMAS K. HAZLET, AND DENISE BOUDREAU

KEY CONCEPTS

1. Risks and benefits are commonly identified only after a drug is widely used by the general population.
2. Observational study designs are essential for the study of risks and benefits associated with marketed drugs.
3. Regulatory agencies are under pressure to identify and respond to postapproval drug safety issues and work with stakeholders on risk management and risk communication.
4. Not all drug–disease associations represent cause–effect relationships.

1 The practice of pharmacotherapy presents numerous challenges to clinicians as they apply knowledge of the benefits and risks of pharmaceuticals to the provision of individual and population-based care. A great deal of our understanding about the efficacy and short-term safety of drugs arises from well-controlled studies conducted during the drug development and approval process. However, many additional risks and, increasingly, additional benefits are only identified after the drug is used widely by the general population. Our gaps in knowledge of risks and benefits at the time a drug is marketed is due to numerous characteristics of premarketing studies, including limited sample size, relatively short study follow-up, restricted characteristics of persons studied, and differences in research settings from real-life conditions once a drug is marketed. Benefits and risks learned following a drug's approval may range from relatively minor to clinically important effects that seriously alter an individual drug's risk-benefit profile. The association between certain appetite-suppressant drugs and primary pulmonary hypertension/valvular heart disease and some cyclooxygenase-2 (COX-2) inhibitors and cardiovascular events are two examples where serious adverse effects were discovered only after these drugs had come into widespread use.[1–4] These examples highlight the inherent limitations of the drug development process, the limitations of contemporary medical product regulatory framework, and the need to study populations using medications, biologics, and medical devices obtained through real-world healthcare delivery. The liver toxicity seen with troglitazone and rosiglitazone is another example of the valuable contribution of close monitoring to drug safety. The first thiazolidinedione introduced for treatment of type 2 diabetes mellitus in 1997, troglitazone was withdrawn from the market based on reports of serious hepatocellular injury. In the mid-2007s, heart attacks and related deaths were observed in pooled clinical trials data for some patients receiving rosiglitazone, another thiazolidinedione subsequently approved for diabetes.[5] Medical products must be monitored closely following their introduction into the marketplace, and this information has value when applied to clinical practice. The purpose of this chapter is to describe the role of pharmacoepidemiology in drug development and therapeutics and to characterize the primary methods and contemporary issues in this field.

CHAPTER 14

Clinical Toxicology

PETER A. CHYKA

KEY CONCEPTS

1. Poisoning can result from exposure to excessive doses of any chemical, with medicines being responsible for most childhood and adult poisonings.
2. The total number and rate of poisonings have been increasing, but preventive measures, such as child-resistant containers, have reduced mortality in young children.
3. Immediate first aid may reduce the development of serious poisoning, and consultation with a poison control center may indicate the need for further therapy.
4. The use of ipecac syrup, gastric lavage, and cathartics has fallen out of favor as routine therapies, whereas activated charcoal and whole-bowel irrigation still are useful for gastric decontamination of appropriate patients.
5. Antidotes can prevent or reduce the toxicity of certain poisons, but symptomatic and supportive care is essential for all patients.
6. Acute acetaminophen poisoning produces severe liver injury and occasionally kidney failure. A determination of serum acetaminophen concentration may indicate whether there is risk of hepatotoxicity and the need for acetylcysteine therapy.
7. Anticholinesterase insecticides may produce life-threatening respiratory distress and paralysis by all routes of exposure and can be treated with symptomatic care, atropine, and pralidoxime.
8. An overdose of calcium channel antagonists will produce severe hypotension and bradycardia and can be treated with supportive care, calcium, insulin with supplemental dextrose, and glucagon.
9. Poisoning with iron-containing drugs produces vomiting, gross gastrointestinal bleeding, shock, metabolic acidosis, and coma and can be treated with supportive care and deferoxamine.
10. Overdoses of tricyclic antidepressants can cause arrhythmias, such as prolonged QRS intervals and ventricular dysrhythmias, coma, respiratory depression, and seizures and are treated with symptomatic care and intravenous sodium bicarbonate.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

Poisoning is an adverse effect from a chemical that has been taken in excessive amounts. The body is able to tolerate and, in some cases, detoxify a certain dose of a chemical; however, once a critical threshold is exceeded, toxicity results. Poisoning can produce minor local effects that can be treated readily in the outpatient setting or systemic life-threatening effects that require intensive medical intervention. This spectrum of toxicity is typical for many chemicals with which humans come in contact. Virtually any chemical can become a poison when taken in sufficient quantity, but the potency of some compounds leads to serious toxicity with small quantities (Table 14–1).[1] Poisoning by chemicals includes exposure to drugs, industrial chemicals, household products, plants, venomous animals, and agrochemicals. This chapter describes some examples of this spectrum of toxicity, outlines means to recognize poisoning risk, and presents principles of treatment.

EPIDEMIOLOGY

Each year poisonings account for approximately 37,000 deaths and at least 1.7 million emergency department visits in the United States.[2,3] Males have a nearly two-fold higher incidence of death than do females and 15% of adult poisoning deaths are attributed to suicide. Approximately 0.2% of poisoning deaths involve children younger than 5 years.[2] Of emergency department visits, typically 31% involve illicit drugs only, 28% involve pharmaceuticals only, 13% involve illicit drugs with alcohol, and 10% involve alcohol with pharmaceuticals.[2] Approximately 40% of emergency department visits for poisoning involve abuse of prescription and nonprescription drugs with one half of these patients taking multiple drugs. The number and rates of poisoning deaths from all circumstances have been increasing steadily, with a 90% overall increase from 1999 to 2006, representing 37,286 deaths in 2006.[3] This increasing mortality trend has placed poisoning as the second leading cause of injury death overall and the leading cause of injury death of people 35 to 54 years of age. Poisoning deaths were most frequently due to drugs. The number of deaths from opioid analgesics has nearly tripled from 1999 to 2006 and opioids were involved in nearly 40% of all poisoning deaths in 2006.[4]

Acids[a]	Cocaine
Anticholinesterase insecticides[a]	Colchicine
Caustics or alkalis[a]	Cyanide[a]
Cationic detergents[a]	Hydrocarbons[a]
Chloroquine	Methanol[a]
Clonidine	Phencyclidine or LSD

[a]Concentrated or undiluted form.

TABLE 14-2 Comparison of Various Poisoning Databases

Database (Abbreviation)	Characteristics
Death certificates from state health departments compiled by the National Center for Health Statistics (NCHS) *www.cdc.gov/injury/wisqars/index.html*	Compiles all death certificates whether the cause of death was by disease or external forces. Typically verified by laboratory and clinical observations
National Electronic Injury Surveillance System – All Injury Program of U.S. Consumer Product Safety Commission (NEISS) *www.cdc.gov/injury/wisqars/index.html*	Surveys electronically all injuries, including poisonings, treated daily at approximately 100 emergency departments. Used to identify product-related injuries
Drug Abuse Warning Network (DAWN) of the Federal Substance Abuse and Mental Health Services Administration (SAMHSA) *www.dawninfo.samhsa.gov*	Identifies substance abuse–related episodes and deaths as reported to approximately 1,100 hospitals and 600 medical examiners
The American Association of Poison Control Centers' National Poison Data System (AAPCC-NPDS) *www.aapcc.org*	Represents largest database of poisonings with high representation of children based on voluntary reporting to poison control centers

1 Several databases in the United States provide different levels of insight into and documentation of the poisoning problem (Table 14–2). Poisonings documented by U.S. poison centers are compiled in the annual report of the American Association of Poison Control Centers' National Poison Data System (AAPCC-NPDS).[5] Although it represents the largest database on poisoning, it is not complete because it relies on individuals voluntarily contacting a poison control center. The AAPCC-NPDS dataset captures approximately 5% of the annual number of deaths from poisoning tabulated in death certificates.[5,6] Despite this shortcoming, AAPCC-NPDS provides valuable insight into the characteristics and frequency of poisonings. In the 2007 AAPCC-NPDS summary, 2,482,041 poisoning exposures were reported by 61 participating poison centers that served the entire United States.[5] Children younger than 6 years accounted for 51% of cases. The home was the site of exposure in 93% of the cases, and a single substance was involved in 91% of cases. An acute exposure accounted for 91% of cases, 83% of which were unintentional or accidental exposures. Only 13% were intentional. Fatalities accounted for 1,239 (0.05%) cases, of which 3% were children younger than 6 years. The distribution of substances most frequently involved in pediatric and adult exposures differed; however, medicines were the most frequently involved (52%) substances (Table 14–3).

TABLE 14-3 Poison Exposure by Age Group and Fatal Outcome, Ranked in Decreasing Order

Pediatric	Adult	Fatal Outcome
Medicines	Medicines	Medicines
Cosmetics, personal care items	Cosmetics, personal care items	Alcohols
Cleaning substances	Cleaning substances	Gases, fumes
Pesticides	Pesticides	Chemicals
Arts and crafts, office supplies	Plants	Automotive products
Alcohols	Arts and crafts, office supplies	Pesticides
Food products	Alcohols	Cleaning substances

From reference Bronstein et al.[5]

Seventy-three percent of the poison exposures were treated at the scene, typically a home. In summary, children account for most of the reported poison exposures, but adults account for a greater proportion of life-threatening effects from poisoning.

ECONOMIC IMPACT OF POISONING

Poisoning accounted for a total lifetime cost of $12.6 billion annually in 2003 dollars.[7] Estimates of the lifetime cost of injury include related healthcare costs and lost lifetime earnings of the victim; however, they do not include the costs of suffering, reduced productivity of caregivers, or legal costs. The definition of poisoning for this economic estimate excluded poisoning from alcohol and illicit drugs.

POISON PREVENTION STRATEGIES

2 The number of poisoning deaths in children has declined dramatically over the past four decades, due, in part, to the implementation of several poison prevention approaches.[7,8] These include the Poison Prevention Packaging Act (PPPA) of 1970, the evolution of regional poison control centers, the application of prompt first aid measures, improvements in overall critical care, development of less toxic product formulations, better clarity in the packaging and labeling of products, and public education on the risks and prevention of poisoning.[9] Although all these factors play a role in minimizing poisoning dangers, particularly in children, the PPPA has perhaps had the most significant influence.[8] The intent of the PPPA was to develop packaging that is difficult for children younger than 5 years to open or to obtain harmful amounts within a reasonable period of time. However, the packaging was not to be difficult for normal adults to use properly. Safety packaging is required for a number of products and product categories (Table 14–4). Child-resistant containers are not totally childproof and may be opened by children, which can result in poisoning. Despite the success of child-resistant containers, many adults disable the hardware or simply use no safety cap, thus placing children at risk. Fatigue of the packaging materials can occur, which underscores the need for new prescription ware for refills, as required in the PPPA.[10]

Poison prevention requires constant vigilance because of new generations of families in which parents and grandparents must be educated on poisoning risks and prevention strategies. New products and changes in product formulations present different poisoning dangers and must be studied to provide optimal management. Strategies to prevent poisonings should consider the various psychosocial circumstances of poisoning (Table 14–5), prioritize risk groups and behaviors, and customize an intervention for specific situations.[11,12]

TABLE 14-4 Examples of Products Requiring Child-resistant Closures

Acetaminophen	Kerosene
Aspirin	Methanol
Diphenhydramine	Naproxen
Ethylene glycol	Oral prescription drugs[a]
Glue removers containing acetonitrile	Sodium hydroxide
Ibuprofen	Sulfuric acid
Iron pharmaceuticals	Turpentine

[a]With certain exceptions such as nitroglycerin and oral contraceptives.

TABLE 14-5 Psychosocial Characteristics of Poisoning Patients

Children	Young Adults	Elderly
Act purposefully or are poisoned by caretaker or sibling	Intentional abuse or suicidal intent is possible	Act with suicidal intent or unintentional misuse
Act with developmentally appropriate curiosity	Disregard or cannot read directions	Confuse product identity and directions for use
Attracted by product appearance	Do not recognize poisoning risk	Do not recognize poisoning risk
Ingest substances that adults find unpleasant	Reluctant to seek assistance until ill	Comorbid conditions complicate toxicity
React to stressful and disrupted household	Exaggerate or misrepresent situation	Unable or unwilling to describe situation
Imitate adult behaviors (e.g., taking medicine)	Peer pressure to experiment with drugs	Multiple drugs may lead to adverse reactions

RECOGNITION AND ASSESSMENT

The clinician's initial responsibility is to determine whether a poisoning has occurred or a potential for development of a poisoning exists. Some patients provide a clear account of an exposure that occurred with a known quantity of a specific agent. Other patients appear with an unexplained illness characterized by nonspecific signs and symptoms and no immediate history of ingestion. Exposure to folk remedies, dietary supplements, and environmental toxins also should be considered. Patients with suicide gestures can deliberately give an unclear history, and poisoning should be suspected routinely. Poisoning and drug overdoses should be suspected in any patient with a sudden, unexplained illness or with a puzzling combination of signs and symptoms, particularly in high-risk age groups. Nearly any symptom can be seen with poisoning, but some signs and symptoms are suggestive of a particular toxin exposure.[13] Compounds that produce characteristic clinical pictures (toxidromes), such as organophosphate poisoning with pinpoint pupils, rales, bradycardia, central nervous system depression, sweating, excessive salivation, and diarrhea, are most readily recognizable.[14] The recognition of chemicals responsible for acute mass emergencies resulting from industrial disasters, hazardous materials accidents, or acts of terrorism may be aided by evaluating characteristic signs and symptoms.[15] Some drugs may be adulterated or counterfeit products and delay appropriate recognition of a possible toxin.[16] Assessment of the patient may be aided by consultation with a poison control center. A center can provide information on product composition, typical symptoms, range of toxicity, laboratory analysis, treatment options, and bibliographic references. Furthermore, a center will have specially trained physicians, pharmacists, nurses, and toxicologists on staff or available for consultation to assist with difficult cases. Consultation with a poison control center also may identify changes in recommended therapy. A nationwide toll-free poison center access number (1-800-222-1222) routes callers to a local poison control center.

When the circumstances of a poison exposure indicate that it is minimally toxic, many poisonings can be managed successfully at the scene of the poisoning.[5,17] Poison control centers typically monitor the victim by telephone during the first 2 to 6 hours of the exposure to assess the patient's status and outcome of first aid.

Once a poisoning is suspected and confirmation of the diagnosis is needed for medical or legal purposes, appropriate biologic material should be sent to the laboratory for analysis. Gastric contents may contain the greatest concentration of drug, but they are difficult to analyze. Blood or urine can be tested by qualitative screening in order to detect a drug's presence.[18,19] The results of a qualitative drug screen can be misleading because of interfering or low-level substances (Table 14–6); it rarely guides emergency therapy and thus has questionable value for nonspecific, general screening purposes.[18,19] Consultation with the laboratory technician and review of the assay package insert will help to determine the sensitivity and specificity of the assay. Quantitative determination of serum concentrations may be important for the assessment of some poisonings, such as those containing acetaminophen, ethanol, methanol, iron, theophylline, and digoxin.[20]

TABLE 14-6 Considerations in Evaluating the Results of Some Common Immunoassays Used for Urine Drug Screening

Drug	Detection After Stopping Use	Comments
Amphetamines	2–5 days	Many sympathomimetic amines, such as pseudoephedrine, ephedra, phenylephrine, fenfluramine, and phentermine, may cause positive results
	Up to 2 weeks with prolonged or heavy use	Other drugs, such as selegiline, chlorpromazine, trazodone, bupropion, and amantadine, may cause false-positive results depending on the assay
Benzodiazepines	Up to 2 weeks Up to 6 weeks with chronic use of some drugs	Ability to detect benzodiazepines varies by drug
Cannabinoid metabolite (marijuana)	7–10 days Up to 1–2 months with prolonged or heavy use	Extent and duration of use will affect detection time. Drugs such as ibuprofen and naproxen may cause false-positive results depending on the assay
Cocaine metabolite (benzoylecgonine)	12–72 hours Up to 1–3 weeks with prolonged or heavy use	Cocaine is metabolized rapidly and specific metabolites are typically the substance detected. False-positive results from "caine" anesthetics and other drugs are unlikely
Opioids	2–3 days Up to 6 days with sustained-release formulations Up to 1 week with prolonged or heavy use	Because the assay was made to detect morphine, detection of other opioids, such as codeine, oxycodone, hydrocodone, and other semisynthetic opioids, may be limited. Some synthetic opioids, such as fentanyl and meperidine, may not be detected. Drugs such as rifampin and some fluoroquinolones may cause false-positive results depending on the assay
Phencyclidine	2–10 days 1 month or more with prolonged or heavy use	Drugs such as ketamine, dextromethorphan, diphenhydramine, and sertraline may cause false-positive results depending on the assay

TABLE 14-7 Examples of the Influence of Drug Overdosage on Pharmacokinetic and Pharmacodynamic Characteristics

Effect of Overdosage[a]	Examples
Slowed absorption due to formation of poorly soluble concretions in the gastrointestinal tract	Aspirin, lithium, phenytoin, sustained-release theophylline
Slowed absorption due to slowed gastrointestinal motility	Benztropine, nortriptyline
Slowed absorption due to toxin-induced hypoperfusion	Procainamide
Decreased serum protein binding Increased volume of distribution associated with toxin-induced acidemia	Lidocaine, salicylates, valproic acid Salicylates
Slowed elimination due to saturation of biotransformation pathways	Ethanol, phenytoin, salicylates, theophylline
Slowed elimination due to toxin-induced hypothermia (<35°C)	Ethanol, propranolol
Prolonged toxicity due to formation of longer-acting metabolites	Carbamazepine, dapsone, glutethimide, meperidine

[a]Compared to characteristics following therapeutic doses or resolution of toxicity.

PHARMACOKINETICS OF OVERDOSE

The pharmacokinetic characteristics of drugs taken in overdose may differ from those observed following therapeutic doses (Table 14–7).[21,22] These differences are the result of dose-dependent changes in absorption, distribution, metabolism, or elimination; pharmacologic effects of the drug; or pathophysiologic consequences of the overdose. Dose-dependent changes may decrease the rate and extent of absorption, whereas the bioavailability of the agent may be increased due to saturation of first-pass metabolism. The distribution of a compound may be altered due to saturation of protein-binding sites. Metabolism and elimination of a compound may be retarded due to saturation of biotransformation pathways leading to nonlinear elimination kinetics. Delayed gastric emptying by anticholinergic drugs or as the result of general central nervous system depression caused by many drugs may alter the rate and extent of absorption. Patients with a drug overdose may inherently exhibit prolonged gastric emptying and gastric hypomotility.[23] The formation of concretions or bezoars of solid dosage forms may delay the onset, prolong the duration, or complicate the therapy for an acute overdose.[24] A combination of pharmacokinetic and pharmacodynamic factors may lead to delayed onset of toxicity of several toxins, such as thyroid hormones, oral anticoagulants, acetaminophen, and drugs in sustained-release dosage forms.[25] Drug-induced hypoperfusion may affect drug distribution and result in reduced hepatic or renal clearance. Changes in blood pH may alter the distribution of weak acids and bases. Drug-induced renal or hepatic injury also can decrease clearance significantly. Implications of these changes for poisoning management include delayed achievement of peak concentrations with a corresponding longer period of opportunity to remove the drug from the gastrointestinal tract. The expected duration of effects may be much greater than that observed with therapeutic doses because of continued absorption and impaired clearance. The application of pharmacokinetic variables, such as percentage protein binding and volume of distribution, from therapeutic doses may not be appropriate in poisoning cases.[21,22] Data on toxicokinetics often are difficult to interpret and compare because the doses and times of ingestion are uncertain, the duration of sampling is inadequate, active metabolites may not be measured, protein binding typically is not assessed, and the severity of toxicity may vary dramatically.

TREATMENT

Clinical Toxicology

GENERAL APPROACHES TO TREATMENT OF THE POISONED PATIENT

PREHOSPITAL CARE

First Aid

3 The presence of adequate airway, breathing, and circulation should be assessed, and cardiopulmonary resuscitation should be started if needed. The most important step in preventing a minor exposure from progressing to a serious intoxication is early decontamination of the poison. Basic poisoning first aid and decontamination measures (Table 14–8) should be instituted immediately at the scene of the poisoning. If there is any question about the potential severity of the poison exposure, a poison control center should be consulted immediately (1-800-222-1222). While awaiting transport, placing the patient on the left side may afford easier clearance of the airway if emesis occurs and may slow absorption of drug from the gastrointestinal tract.[26]

Ipecac Syrup

4 Ipecac syrup, a nonprescription drug, has been used in the United States for the past 50 years as a means to induce vomiting for treatment of ingested poisons. Despite its widespread use, concerns about its effectiveness and safety have been raised recently. An expert panel of North American and European toxicologists concluded that its routine use in the emergency department should be abandoned.[27] In 2003 the American Academy of Pediatrics issued a policy statement indicating that ipecac syrup was no longer to be used routinely to treat poisonings at home and that parents should discard any ipecac.[28] The key reason for the policy change was that research failed to show benefits in children who were treated with ipecac syrup. It likely will take several years for these recommendations to be adopted fully by parents and healthcare professionals, and rare exceptions may arise. In the 2007 AAPCC-NPDS report, 0.07% of 2.48 million cases received ipecac syrup, with or without poison center direction.[5]

There are several contraindications to the use of ipecac syrup or any form of induced emesis, such as gagging.[27] If the patient is without a gag reflex; is lethargic, comatose, or convulsing; or is expected to become unresponsive within the next 30 minutes, emesis should not be induced. If a fruitful emesis has occurred

TABLE 14-8 First Aid for Poison Exposures

Inhaled poison	Immediately get the person to fresh air. Avoid breathing fumes. Open doors and windows. If victim is not breathing, start artificial respiration.
Poison on the skin	Remove contaminated clothing and flood skin with water for 10 minutes. Wash gently with soap and water and rinse. Avoid further contamination of victim or first aid providers.
Poison in the eye	Flood the open eye with lukewarm or cool water poured from a glass 2 or 3 inches from the eye. Repeat for 10–15 continuous minutes. Remove contact lenses.
Swallowed poison	Unless the patient is unconscious, having convulsions, or cannot swallow, give 2–4 ounces of water immediately and then seek further help.

spontaneously shortly after ingestion, further emesis may not be necessary. Ingestions of caustics, corrosives, ammonia, and bleach are definite contraindications to induced emesis. Ingestion of aliphatic hydrocarbons (e.g., gasoline, kerosene, and charcoal lighter fluid) typically does not require emesis. When the agent is definitely known to be nontoxic, induction of emesis is purposeless and potentially dangerous. The rapid onset of coma or seizures or the potential to exaggerate the toxic effects of the poison may preclude further the induction of emesis. Some examples include poisonings with diphenoxylate, propoxyphene, clonidine, tricyclic antidepressants, hypoglycemic agents, nicotine, strychnine, β-blocking agents, and calcium channel blockers. Debilitated, pregnant, and elderly patients may be further compromised by induction of emesis.

HOSPITAL TREATMENT

General Care

Supportive and symptomatic care is the mainstay of treatment of a poisoned patient. In the search for specific antidotes and methods to increase excretion of the drug, attention to vital signs and organ functions should not be neglected. Establishment of adequate oxygenation and maintenance of adequate circulation are the highest priorities. Other components of the acute supportive care plan include the management of seizures, arrhythmias, hypotension, acid-base balance, fluid status, electrolyte balance, and hypoglycemia. Placement of intravenous and urinary catheters is typical to ensure delivery of fluids and drugs when necessary and to monitor urine production, respectively.[13,14]

Gastric Lavage

Gastric lavage involves the placement of an orogastric tube and washing out of the gastric contents through repetitive instillation and withdrawal of fluid. Gastric lavage may be considered only if a potentially toxic agent has been ingested within the past hour for most patients. If the patient is comatose or lacks a gag reflex, gastric lavage should be performed only after intubation with a cuffed or well-fitting endotracheal tube. The largest orogastric tube that can be passed (external diameter at least 12 mm in adults and 8 mm in children) should be used to ensure adequate evacuation, especially of undissolved tablets. Lavage should be performed with warm (37°C–38°C) normal saline or tap water until the gastric return is clear; this usually requires 2 to 4 L or more of fluid. Relative contraindications for gastric lavage include ingestion of a corrosive or hydrocarbon agent. Complications of gastric lavage include aspiration pneumonitis, laryngospasm, mechanical injury to the esophagus and stomach, hypothermia, and fluid and electrolyte imbalance.[29] Use of gastric lavage has declined in recent years as evidenced by the finding that only 1.5% of 588,262 cases treated at a healthcare facility received gastric lavage in the 2007 AAPCC-NCDS report.[5]

Single-Dose Activated Charcoal

Reduction of toxin absorption can be achieved by administration of activated charcoal. It is a highly purified, adsorbent form of carbon that prevents gastrointestinal absorption of a drug by chemically binding (adsorbing) the drug to the charcoal surface. There are no toxin-related contraindications to its use, but it is generally ineffective for iron, lead, lithium, simple alcohols, and corrosives. It is not indicated for aliphatic hydrocarbons because of the increased risk for emesis and pulmonary aspiration. Activated charcoal is most effective when given within the first few hours after ingestion, ideally within the first hour.[30] The recommended dose of activated charcoal for a child (1 to 12 years old) is 25 to 50 g; for an adolescent or adult the recommended dose is 25 to 100 g. Children younger than 1 year can receive 1 g/kg.[9] Activated charcoal is mixed with water to make a slurry, shaken vigorously, and administered orally or via a nasogastric tube. Activated charcoal is contraindicated when the gastrointestinal tract is not intact. Activated charcoal is relatively nontoxic, but two identified risks are (a) emesis following administration and (b) pulmonary aspiration of charcoal and gastric contents leading to pneumonitis in patients with an unprotected airway or absent gag reflex.[30] Some activated charcoal products contain sorbitol, a cathartic that may be associated with an increased incidence of emesis following use.[31] Single-dose activated charcoal use has remained relatively steady during the past decade, with 4.1% of 2.48 million cases having received it according to the 2007 AAPCC-NPDS report.[5]

CLINICAL CONTROVERSY

Activated charcoal has been promoted for use at home as a replacement for ipecac syrup, but some have contended that little evidence indicates activated charcoal can be used safely and properly in this setting.

Cathartics

Cathartics, such as magnesium citrate and sorbitol, were thought to decrease the rate of absorption by increasing gastrointestinal elimination of the poison and the poison-activated charcoal complex, but their value is unproven. Poisoned patients do not routinely require a cathartic, and it is rarely, if ever, given without concurrent activated charcoal administration.[32] If used, a cathartic should be administered only once and only if bowel sounds are present. Infants, the elderly, and patients with renal failure should be given saline cathartics cautiously, if at all.[9,32]

Whole-Bowel Irrigation

Polyethylene glycol electrolyte solutions, such as GoLYTELY and Colyte, are used routinely as whole-bowel irrigants prior to colonoscopy and bowel surgery.[33] These solutions also can be used to decontaminate the gastrointestinal tract of ingested toxins.[9,13,34] Large volumes of these osmotically balanced solutions are administered continuously through a nasogastric or duodenal tube for 4 to 12 hours or more. They quickly cause gastrointestinal evacuation and are continued until the rectal discharge is relatively clear. This procedure may be indicated for certain patients in whom the ingestion occurred several hours prior to hospitalization and the drug still is suspected to be in the gastrointestinal tract, such as drug smugglers who swallow condoms filled with cocaine.[35] In addition, patients who have ingested delayed-release or enteric-coated drug formulations or have ingested substances such as iron that are not well adsorbed by activated charcoal may benefit from whole-bowel irrigation.[34] It should not be used in patients with a bowel perforation or obstruction, gastrointestinal hemorrhage, ileus, or intractable emesis. Emesis, abdominal cramps, and intestinal bloating have been reported with whole-bowel irrigation.[34] During 2007, whole-bowel irrigation was used in 0.5% of 588,262 cases managed at a healthcare facility.[5]

CLINICAL CONTROVERSY

Some clinicians believe that whole-bowel irrigation should be used more routinely as a rapid means to evacuate the gastrointestinal tract. Others recognize that it does have a quick onset but point out that little proof indicates whole-bowel irrigation makes a difference in patient outcome.

Perspectives on Gastric Decontamination

Although there are a variety of options for gastric decontamination, two clinical toxicology groups (the American Academy of Clinical Toxicology and the European Association of Poison Centers and Clinical Toxicologists) have concluded that no means of gastric decontamination should be used routinely for a poisoned patient without careful consideration.[27,29,30,32,34] They indicate that therapy is most effective within the first hour and that effectiveness beyond this time cannot be supported or refuted with the available data. A clinical policy statement by the American College of Emergency Physicians concludes that although no definitive recommendation can be made on the use of ipecac syrup, gastric lavage, cathartics, or whole-bowel irrigation, activated charcoal is advocated for most patients when appropriate.[36] The clinical policy also states that ipecac syrup is rarely of value in the emergency department and that the use of whole-bowel irrigation following ingestion of substances not well adsorbed by activated charcoal is not supported by evidence. The efficacy of activated charcoal has been demonstrated for many compounds,[30] but a randomized, controlled clinical trial of poisoned patients indicated that charcoal therapy did not reduce length of hospital stay or positively influence patient outcomes.[37] Although gastric lavage can reduce drug absorption if performed within 1 hour of ingestion, its use is not recommended routinely.[29,36,38] In recent years, the use of ipecac syrup has declined markedly in part because of its apparent lower efficacy compared with activated charcoal in minimizing drug absorption.[5,27,30] The American Academy of Pediatrics has recommended that ipecac syrup no longer be used for treatment of poisonings at home and has called for its removal from the home.[28] Recently, activated charcoal has been promoted for treatment of poisonings at home, but issues of safety, patient compliance, and effectiveness have not been proven in the home setting.[1,28,39] Poison control centers may be a source of guidance on the contemporary application of gastric decontamination techniques for a specific patient.

Enhanced Elimination Numerous methods have been used to increase the rate of excretion of poisons from the body. Of these, only diuresis, multiple-dose activated charcoal, and hemodialysis have demonstrated usefulness. These approaches should be considered only if the risks of the procedure are significantly outweighed by the expected benefits or if the recovery of the patient is seriously in doubt and the method has been shown to be helpful.

Diuresis Diuresis can be used for poisons excreted predominantly by the renal route; however, most drugs and poisons are metabolized, and only a good urine flow (e.g., 2–3 mL/kg/h) needs to be maintained for most patients. Fluid and electrolyte balance should be monitored closely. Ionized diuresis by altering urinary pH may increase excretion of certain chemicals that are weak acids or bases by trapping ionized drug in the renal tubule and minimizing reabsorption.[13] Alkalinization of the urine to achieve a urine pH of 7.5 or greater for poisoning by weak acids such as salicylates or phenobarbital can be achieved by intravenous administration of sodium bicarbonate 1 to 2 mEq/kg (1–2 mmol/kg) over a 1- to 2-hour period. Complications of urinary alkalinization include alkalosis, fluid and electrolyte disturbances, and inability to achieve target urinary pH values.[40] Acid diuresis may enhance the excretion of weak bases, such as amphetamines, but it is rarely, if ever, used because it risks worsening rhabdomyolysis commonly associated with amphetamine overdose.[13] Generally, diuresis or ionized diuresis is rarely indicated for poisoned patients because it is inefficient relative to other methods of enhancing elimination, it is associated with a risk of unacceptable adverse effects, and renal elimination of most drugs is not enhanced dramatically.

Multiple-Dose Activated Charcoal Multiple doses of activated charcoal can augment the body's clearance of certain drugs by enhanced passage from the bloodstream into the gastrointestinal tract and subsequent adsorption. This process, termed *charcoal intestinal dialysis* or *charcoal-enhanced intestinal exsorption,* describes the attraction of drug molecules across the capillary bed of the intestine by activated charcoal in the intestinal lumen and subsequent adsorption of the drug to the charcoal.[41] Furthermore, it may interrupt the enterohepatic recirculation of certain drugs.[13,41] Once the drug is adsorbed to the charcoal, it is eliminated with the charcoal in the stool. Systemic clearance of several drugs has been shown to be enhanced up to several-fold.[41,42] An international toxicology group's position statement on multiple-dose activated charcoal concluded that it should be considered only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline.[42] Although a prospective, randomized study of the effects of multiple-dose activated charcoal on phenobarbital-overdosed patients demonstrated increased drug elimination, no demonstrable effect on patient outcome was observed.[43]

This approach provides a rapid onset of action that is limited by blood flow and a maximal "ceiling effect" related to the dose of charcoal present in the intestine. The response to multiple-dose activated charcoal is greatest for drugs with the following characteristics: good affinity for adsorption by activated charcoal, low intrinsic clearance, sufficient residence time in the body (long serum half-life), long distributive phase, and nonrestrictive protein binding. A small volume of distribution is desirable, but it has a marginal influence as an isolated characteristic,[44] particularly if multiple-dose activated charcoal is instituted during the toxin's distributive phase. A typical dosage schedule is 15 to 25 g of activated charcoal every 2 to 6 hours until serious symptoms abate or the serum concentration of the toxin is below the toxic range. This procedure has been used in premature and full-term infants in doses of 1 g/kg every 1 to 4 hours. Serious complications, such as pulmonary aspiration, occur in <1% of patients.[45] The risks of aspiration pneumonitis in obtunded or uncooperative patients and of intestinal obstruction in patients prone to ileus following a period of bowel ischemia (e.g., after cardiopulmonary arrest in the elderly) may be higher.[46] Contraindications are the same as those for single-dose charcoal.

Hemodialysis Hemodialysis may be necessary for certain severe cases of poisoning. Dialysis should be considered when the duration of symptoms is expected to be prolonged, normal pathways of excretion are compromised, clinical deterioration is present, the drug is dialyzable, and appropriate personnel and equipment are available. Drugs that are hemodialyzable usually have a low molecular weight, are not highly or tightly protein bound, and are not highly distributed to tissues. The principles of hemodialysis for acutely ill individuals are described in Chapter 54. Hemodialysis and charcoal hemoperfusion are efficient methods of dialysis, but both pose serious risks related to anticoagulation, blood transfusions, loss of blood elements, fluid and electrolyte disturbances, and infection.[47] Hemodialysis may be lifesaving for methanol and ethylene glycol poisoning and effective for other poisons, such as lithium, salicylates, ethanol, and theophylline.[13,36] Charcoal hemoperfusion was popular in the 1970s and 1980s as a means to remove toxins, but this approach has fallen out of favor because of poor clinical results, inappropriate use for drugs with large volumes of distribution, and limited availability of charcoal hemoperfusion columns.[48] Continuous hemofiltration transports drugs across a semipermeable membrane by convection in response to hydrostatic pressure gradients.[13,47] Limited experience is reported with the use of hemofiltration for poisonings, but it may be attractive

TABLE 14-9 Systemic Antidotes Available in the United States

Toxic Agent	Antidote
Acetaminophen	Acetylcysteine
Anticholinesterase insecticides	Atropine
Anticoagulants	Phytonadione
Benzodiazepines	Flumazenil
Botulism	Botulism antitoxin
Carbon monoxide	Oxygen
Cyanide	Cyanide antidote kit (amyl nitrite, sodium nitrate, and sodium thiosulfate)
Cyanide	Hydroxocobalamin
Digoxin	Digoxin immune Fab
Ethylene glycol, methanol	Ethanol
Ethylene glycol, methanol	Fomepizole
Heavy metals (copper, lead)	Dimercaprol
Heavy metals (copper, lead)	Penicillamine
Iron	Deferoxamine
Isoniazid	Pyridoxine
Lead	Calcium EDTA
Lead	Succimer
Methemoglobinemia	Methylene blue
Opioids	Nalmefene
Opioids	Naloxone
Organophosphate insecticides	Pralidoxime
Radioactive americium, curium, plutonium	Diethylenetriamene pentaacetate
Radioactive iodine	Potassium iodide
Snake, coral	*Micrurus fulvius* antivenin
Snakes (rattlesnakes, cottonmouth, copperhead)	*Crotalidae* polyvalent antivenin *Crotalidae* polyvalent immune Fab
Spider, black widow	*Lactrodectus mactans* antivenin
Thallium	Prussian blue

for the hemodynamically unstable patient who cannot tolerate hemodialysis.

Antidotes

5 The search for and use of an antidote should never replace good supportive care.[36] Specific systemic antidotes are available for many common poisonings (Table 14–9).[49,50] Inadequate availability of antidotes at acute care hospitals has been noted throughout the United States and can complicate the care of a poisoned patient. An evidenced-based consensus of experts has recommended minimum stocking requirements for 24 antidotes for acute care hospitals and that 12 be available for immediate administration upon patient arrival.[51] These recommendations may provide guidance to pharmacy and therapeutics committees in establishing a hospital's antidote needs. Drugs used conventionally for nonpoisoning situations may act as antidotes to reverse acute toxicity, such as insulin-dextrose or glucagon for β-adrenergic blocker or calcium channel antagonist overdose and octreotide for sulfonylurea-induced hypoglycemia.[52] As our understanding of drug toxicity increases, antidotes may have applications beyond contemporary indications, such as for acetylcysteine, which has shown promise for treating approximately 25 different poisonings and adverse drug reactions.[53] Commercially available intravenous lipid emulsions, e.g. Intralipid, have recently been used to reduce cardiac toxicity from several lipid-soluble drugs.[54] The use of toxin-specific antibodies (e.g., fragment antigen binding [Fab] antibody fragments for digoxin[55] or crotalid snake venom[56]) has offered a new approach to treatment of poisoning victims.

Assessing the Effectiveness of Therapies

Our knowledge of poisoning treatment is derived from case reports, clinical studies, human volunteer studies, animal investigations, and in vitro tests. Each of these approaches has limited applicability to the care of humans who have been poisoned. Case reports often are difficult to assess because they are uncontrolled, the histories are uncertain, and multiple therapies frequently are used. However, they can be useful to describe unique or new toxicities or characterize adverse effects associated with a therapy. Although clinical studies may describe tens to hundreds of patients, they can exhibit serious shortcomings, such as weak randomization procedures, no laboratory confirmation or correlation with history, insufficient number of severe cases, no control group, and no quantitative measure of outcome. Extrapolation of data from human volunteer studies to patients who overdose is difficult because of potential or unknown variations in pharmacokinetics (e.g., differing dissolution, gastric emptying, and absorption rates) seen with toxic as opposed to therapeutic doses,[21,22] differences in time to institute therapy in the emergency setting, and differences in absorption in fasted human volunteers compared with the full stomach of some patients who overdose. However, these studies provide the most controlled and objective measures of the efficacy of a treatment. Experiences from animal studies cannot be applied directly to humans because of interspecies differences in toxicity and metabolism. In vitro tests serve to screen the efficacy of some approaches, such as activated charcoal adsorption, but they do not mimic physiologic conditions sufficiently to allow direct clinical application of the findings. Despite their limitations, these data compose the basis for the therapy of poisoned patients and are tempered with the consideration of nonpoisoning-related factors such as a particular patient's underlying medical condition, age, and need for concurrent supportive measures.

CLINICAL SPECTRUM OF POISONING

Poisoning and drug overdose with acetaminophen, anticholinesterase insecticides, calcium channel blockers, iron, and tricyclic antidepressants are the focus of the remainder of this chapter because they represent commonly encountered poisonings for which pharmacotherapy is indicated. These agents also were chosen because they represent common examples with different mechanisms of toxicity, and they illustrate the application of general treatment approaches as well as some agent-specific interventions.

ACETAMINOPHEN

Clinical Presentation

6 Acute acetaminophen poisoning characteristically results in hepatotoxicity[57,58] and is the leading cause of acute liver failure in the United States.[59] Clinical presentation (see below) is dependent on the time since ingestion, presence of risk factors, and the ingestion of other drugs. During the first 12 to 24 hours after ingestion, nausea, vomiting, anorexia, and diaphoresis may be observed; however, many patients are asymptomatic. During the next 1 to 3 days, which is a latent phase of lessened symptoms, patients often have an asymptomatic rise in liver enzymes and bilirubin. Signs and symptoms of hepatic injury become manifest 3 to 5 days after ingestion and include right upper quadrant abdominal tenderness, jaundice, hypoglycemia, and encephalopathy. Prolongation of the international normalized ratio (INR) worsens as hepatic necrosis progresses and may lead to disseminated intravascular coagulopathy.

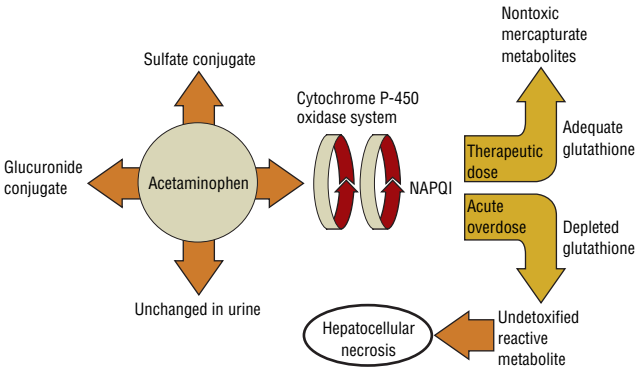

FIGURE 14-1. Pathway of acetaminophen metabolism and basis for hepatotoxicity. (NAPQI, *N-acetyl-p*-benzoquinoneimine, a reactive acetaminophen metabolite.)

Patients with hepatic damage may develop hepatic coma and hepatorenal syndrome, and death can occur.[57,58,60] Survivors of severe hepatotoxicity usually exhibit no residual functional or histologic abnormalities of the liver within 1 to 6 months of the incident.[58]

Mechanism of Toxicity

Acetaminophen is metabolized in the liver primarily to glucuronide or sulfate conjugates, which are excreted into the urine with small amounts (<5%) of unchanged drug. Approximately 5% of a therapeutic dose is metabolized by the cytochrome P450 mixed-function oxygenase system, primarily CYP2E1, to a reactive metabolite, *N*-acetyl-*p*-benzoquinoneimine (NAPQI). This metabolite normally is conjugated with glutathione, a sulfhydryl-containing compound, in the hepatocyte and excreted in the urine as a mercapturate conjugate (Fig. 14–1).[60]

In an acute overdose situation, sulfate stores are depleted, shifting more drug through the cytochrome system, thereby depleting the available glutathione used to detoxify the reactive metabolite. The reactive metabolite NAPQI then reacts with other hepatocellular sulfhydryl compounds such as those in the cytosol, cell wall, and endoplasmic reticulum. This results in centrilobular hepatic necrosis.[60] Several other mechanisms, such as cytokine release and oxidative stress, also may be initiated by the initial cellular injury.[60]

In many cases of severe hepatotoxicity, renal injury also is present and may range from oliguria to acute renal failure. The etiology of the renal injury may be a direct effect of the toxic metabolite of acetaminophen, NAPQI, generated by renal cytochrome oxidase, or a consequence of hepatic injury resulting in hepatorenal syndrome.[61]

Causative Agents

Acetaminophen, also known as paracetamol, is available widely without prescription as an analgesic and antipyretic. It is available in various oral dosage forms, including extended-release preparations. Acetaminophen may be combined with other drugs, such as antihistamines or opioid analgesics, and marketed in cough and cold preparations, menstrual remedies, and allergy products. Some patients may not recognize that they are consuming several products containing acetaminophen which can increase the total daily dose taken and the subsequent risk of hepatotoxicity.

Incidence

Acetaminophen is one of the drugs most commonly ingested by small children and is used commonly in suicide attempts by adolescents and adults. The 2007 AAPCC-NPDS report documented 50,758 nonfatal single-drug product exposures and 74 deaths from acetaminophen alone or in combination products, with 27% of the exposures in children younger than 6 years.[5]

Age-based differences in the metabolism of acetaminophen appear to be responsible for major differences in the incidence of serious toxicity. Despite the common ingestion of acetaminophen by young children, few develop hepatotoxicity from acute overdosage.[5] In children younger than 9 to 12 years, acetaminophen undergoes more sulfation and less glucuronidation. The reduced fraction available for metabolism by the cytochrome system may explain the rare development of serious toxicity in young children who take large overdoses. Earlier treatment intervention and spontaneous emesis also may reduce the risk of toxicity in children.

CLINICAL PRESENTATION OF ACUTE ACETAMINOPHEN POISONING

General

- No or mild nonspecific symptoms within 6 hours of ingestion

Symptoms

- Nausea, vomiting, and abdominal discomfort within 1 to 12 hours after ingestion
- Right upper abdominal quadrant tenderness, typically within 1 to 2 days

Signs

- Typically no signs present within first day
- Jaundice, scleral icterus, bleeding within 3 to 10 days
- Oliguria occasionally within 2 to 7 days
- With severe poisoning, hepatic encephalopathy (delirium, depressed reflexes, coma) within 5 to 10 days

Laboratory Tests

- Toxic serum acetaminophen concentration no earlier than 4 hours after ingestion by comparison with nomogram
- Elevated aspartate aminotransferase (AST), alanine aminotransferase (ALT), serum bilirubin, and international normalized ratio (INR); hypoglycemia within 1 to 3 days
- Elevated serum creatinine and blood urea nitrogen (BUN) within 2 to 7 days

Risk Assessment

There is a risk of developing hepatotoxicity when patients 6 years or older acutely ingest at least 10 g or 200 mg/kg, whichever is less, of acetaminophen or when children younger than 6 years acutely ingest 200 mg/kg or more.[62] Patients have survived much larger doses, particularly with early treatment. Initial symptoms, if present, do not predict how serious the toxicity eventually may become.

Chronic exposure to drugs that induce the cytochrome oxidase system—specifically isoenzyme CYP2E1, which is responsible for most of the formation of NAPQI—may increase the risk of acetaminophen hepatotoxicity. Poorer outcomes have been noted in patients who chronically ingest alcohol and those receiving anticonvulsants, both known to induce CYP2E1.[58,63] Patients with chronic alcoholism have a 3.5 greater odds of mortality with acute acetaminophen poisoning.[64] Concurrent acute ingestion of alcohol and acetaminophen may decrease the risk of acetaminophen-induced hepatotoxicity by ethanol acting as a competitive substrate for CYP2E1, thus reducing NAPQI formation.[65] Ethanol coingestion is

not advocated as a preventive measure, and it is difficult to account for its specific impact on care.

Repeated ingestion of supratherapeutic doses of acetaminophen (defined for patients <6 years: ≥200 mg/kg over 8 to 24 hours, ≥150 mg/kg/day for 2 days, ≥100 mg/kg/day for 3 days or longer; for patients ≥6 years: ≥10 g or 200 mg/kg (whichever is less) over a single 24-hour period, ≥6 g or 150 mg/kg (whichever is less) per 24-hour period for ≥48 hours) has been associated with hepatotoxicity.[58,62] Patients who are fasting or have ingested alcohol in the preceding 5 days appear to be at greater risk.[66] Young children who receive repetitive supratherapeutic doses of acetaminophen have a higher risk of developing hepatotoxicity, particularly when they have been acutely fasting as the result of a febrile illness or gastroenteritis.[62,67] Patients with suspected risk factors, such as alcoholism, isoniazid therapy, or prolonged fasting, should be referred for medical evaluation if there is evidence that the ingestion exceeded 4 g/day or 100 mg/kg/day, whichever is less.[62]

The risk of developing hepatotoxicity may be predicted from a nomogram (Fig. 14–2) based on the acetaminophen serum concentration and time after ingestion.[57,59] The treatment line of the nomogram (150 mcg/mL [1,000 mmol/L] at 4 hours), which allows a margin of error in laboratory analysis and time of ingestion, should be used to make treatment decisions. The other lines on the nomogram indicate differing levels of risk for hepatotoxicity based on a multicenter study of 11,195 patients.[57,68]

If the plasma concentration plotted on the nomogram falls above the nomogram treatment line, indicating that hepatic damage is possible, a full course of treatment with acetylcysteine is indicated. When the results of the acetaminophen determination will be available later than 8 hours after the ingestion, acetylcysteine therapy should be initiated based on the history and later discontinued if the results indicate nontoxic concentrations. The nomogram has not been evaluated and thus is not useful for assessing chronic exposure to acetaminophen. Some have advocated that patients with chronic alcoholism should be treated with acetylcysteine regardless of the risk estimation.[64,68]

Management of Toxicity

Therapy of an acute acetaminophen overdose depends on the amount ingested, time after ingestion, and serum concentration of acetaminophen. When excessive amounts are ingested, the history is unclear, or an intentional ingestion is suspected, the patient should be evaluated at an emergency department and acetaminophen serum concentrations obtained.[62] No prehospital care generally is indicated, and ipecac syrup typically is not recommended.[62] If the patient presents to the emergency department within 4 hours of the ingestion or ingestion of other drugs is suspected, one dose of activated charcoal can be administered.

Acetylcysteine (also known as *N*-acetylcysteine), a sulfhydryl-containing compound, replenishes the hepatic stores of glutathione by serving as a glutathione surrogate that combines directly with reactive metabolites or by serving as a source of sulfate, thus preventing hepatic damage.[69] It should be started within 10 hours of the ingestion to be most effective.[57] Initiation of therapy 24 to 36 hours after the ingestion may be of value in some patients, particularly those with measurable serum acetaminophen concentrations.[69,70] Patients with fulminant hepatic failure may benefit through other mechanisms by the administration or initiation of acetylcysteine several days after ingestion.[69]

Therapy should be initiated with acetylcysteine within 10 hours of ingestion when indicated. The oral liquid was the only approved form of acetylcysteine in the United States until 2004, when the Food and Drug Administration (FDA) approved an intravenous formulation.[71] The dosage regimen for the intravenous form is based on one used in Europe for two decades, and outcomes similar to the 72-hour oral regimen have been reported.[53,71] A systematic review of the literature indicated that acetylcysteine is superior to supportive care, but there is no clear evidence of which regimen is better.[73] There are several notable differences between the oral and intravenous forms of acetylcysteine (Table 14–10),[53,57,71,72] most notable is the occurrence (approximately 10% of cases) of anaphylactoid reactions (see Chapter 97) following the intravenous infusion. An equal number of patients were treated with the intravenous or oral forms of acetylcysteine

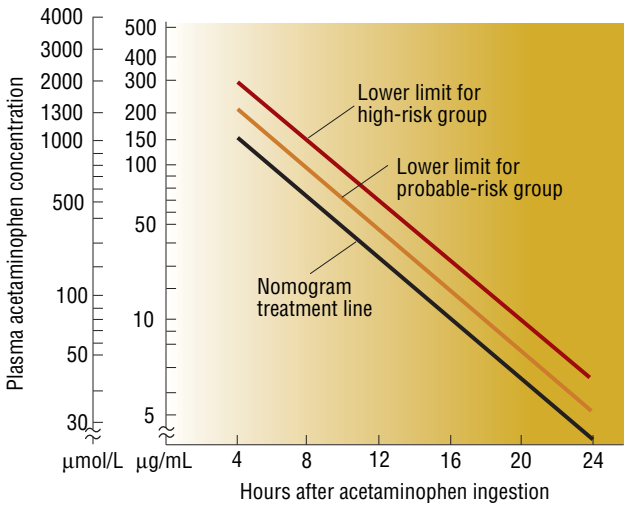

FIGURE 14-2. Nomogram for assessing hepatotoxic risk following acute ingestion of acetaminophen. (*Adapted from Smilkstein MJ, Knapp GL, Kulig KW, Rumack BH. Efficacy of oral N-acetylcysteine in the treatment of acetaminophen overdose: Analysis of the national multicenter study (1976–1985). N Engl J Med 1988;319:1557–1562. TABLE 14-10 Comparison of Intravenous and Oral Regimens for Acetylcysteine in the Treatment of Acute Acetaminophen Poisoning

Characteristic	Intravenous	Oral
Regimen	150 mg/kg in 200 mL D_5W infused over 1 hour, then 50 mg/kg in 500 mL D_5W over 4 hours, followed by 100 mg/kg in 1,000 mL D_5W over 16 hours[a]	140 mg/kg, followed 4 hours later by 70 mg/kg every 4 hours for 17 doses diluted to 5% with juice or soft drinks
Total dose (mg/kg)	300	1,330
Duration (h)	21	72
Adverse effects	Anaphylactoid reactions (rash, hypotension, wheezing, dyspnea); acute flushing and erythema in first hour of the infusion that typically resolves spontaneously	Nausea, vomiting
Ancillary therapy, if needed	Antihistamines and epinephrine for severe anaphylactic reactions	Antiemetics, e.g., metoclopramide, ondansetron, or droperidol
Trade name	Acetadote	Mucomyst
Available strength	20%	10%, 20%

[a]For patients <40 kg and those requiring fluid restriction, the total volume for dilution should be reduced as directed in the package insert.

D_5W, 5% dextrose in water for injection.

as reported in the 2007 AAPCC-NPDS.[5] When acetaminophen plasma concentrations are below the nomogram treatment line, there is little risk of toxicity, protective therapy with acetylcysteine is not necessary, and medical therapy likely is unnecessary.[57] The acetaminophen blood sample should be drawn no sooner than 4 hours after the ingestion to ensure that peak acetaminophen concentrations have been reached. If a concentration is obtained less than 4 hours after ingestion, it is not interpretable, and a second determination should be done at least 4 hours after ingestion. Serial determinations of a serum concentration, 4 to 6 hours apart, typically are unnecessary unless there is some evidence of slowed gastrointestinal motility as the result of the ingestion of certain drugs (e.g., opioids, antihistamines, or anticholinergics) or unless an extended-release product is involved. In these circumstances, therapy with acetylcysteine is continued if any concentration is above the treatment line of the nomogram, and provisional therapy is discontinued when both concentrations are below the treatment line.

Although young children have an inherently lower risk of acetaminophen-induced hepatotoxicity, these patients should be managed in the same manner as adults. When acetaminophen serum concentrations predict that toxicity is probable, young children should receive acetylcysteine in the dosing regimen described previously.[67] If fulminant hepatic failure develops, the approaches described in Chapter 44 should be considered. In unresponsive patients, liver transplantation is a lifesaving option.[58]

CLINICAL CONTROVERSY

The routine administration of acetylcysteine more than 24 hours after acetaminophen overdose has been proposed. Case reports and animal studies indicate that it is relatively safe and that its use may minimize hepatotoxicity. Although accepted criteria for its use are lacking, it may be considered for patients with fulminant hepatoxicity, when acetaminophen is still measurable in the serum, or when the ingestion was not recognized within 24 hours and liver toxicity is apparent.

Monitoring and Prevention

Baseline liver function tests (AST, ALT, bilirubin, INR), serum creatinine determination, and urinalysis should be obtained on admission and repeated at 24-hour intervals until at least 96 hours have elapsed for patients at risk. Most patients with liver injury develop elevated transaminase concentrations within 24 hours of ingestion. AST or ALT concentrations >1,000 international units per liter (>16.7 mkat/L) commonly are associated with other signs of liver dysfunction and have been used as the threshold concentration in outcome studies to define severe liver toxicity.[57] The extent of transaminase elevation is not correlated directly with the severity of hepatic injury, with nonfatal cases demonstrating peak concentrations as high as 30,000 international units per liter (500 mkat/L) between 48 and 72 hours after ingestion.[58]

Prevention of acetaminophen poisoning is based on recognition of the maximum daily therapeutic doses (4 g in adults), observance of general poison prevention practices, and early intervention in cases of suspected overdose. The frequent involvement of acetaminophen in poisonings and overdoses, whether or not declared by the patient, has led to the routine determination of acetaminophen concentrations in patients admitted to emergency departments for any overdose.[18]

ANTICHOLINESTERASE INSECTICIDES

Clinical Presentation

7 The clinical manifestations of anticholinesterase insecticide poisoning include any or all of the following: pinpoint pupils, excessive lacrimation, excessive salivation, bronchorrhea, bronchospasm and expiratory wheezes, hyperperistalsis producing abdominal cramps and diarrhea, bradycardia, excessive sweating, fasciculations and weakness of skeletal muscles, paralysis of skeletal muscles (particularly those involved with respiration), convulsions, and coma.[74] Symptoms of anticholinesterase poisoning and their response to antidotal therapy depend on the action of excessive acetylcholinesterase at different receptor types (Table 14–11).

The time of onset and severity of symptoms depend on the route of exposure, potency of the agent, and total dose received (see presentation box below). Toxic signs and symptoms develop most rapidly after inhalation or intravenous injection and slowest after skin contact. Anticholinesterase insecticides are absorbed through the skin, lungs, conjunctivae, and gastrointestinal tract. Severe symptoms can occur from absorption by any route. Most patients are symptomatic within 6 hours, and death may occur within 24 hours without treatment. Death typically is caused by respiratory failure resulting from the combination of pulmonary and cardiovascular effects (Fig. 14–3).[74] Poisoning may be complicated by aspiration pneumonia, urinary tract infections, and sepsis.[74,75]

Organophosphate poisoning has been associated with several residual effects, such as intermediate syndrome, extrapyramidal symptoms, neuropsychiatric effects, and delayed chronic neuropathy. Intermediate syndrome becomes manifest in some patients approximately 1 to 3 days after exposure and generally resolves within weeks of onset without further treatment. It is characterized by muscle weakness of proximal limbs, cranial nerve innervated muscles, and muscles of respiration. The inability of the patient to raise his or her head is often an initial sign. Extrapyramidal symptoms, which may develop 1 to 7 days after exposure, usually resolve spontaneously within a few days of onset. Neuropsychiatric effects, such as confusion, lethargy, memory impairment, headache, and depression, typically begin weeks to months after exposure and may last for years. Chronic

TABLE 14-11 Effects of Acetylcholinesterase Inhibition at Muscarinic, Nicotinic, and CNS Receptors

Muscarinic receptors	**Nicotinic-sympathetic neurons**
Diarrhea	Increased blood pressure
Urination	Sweating and piloerection
Miosis[a]	Mydriasis[a]
Bronchorrhea	Hyperglycemia
Bradycardia[a]	Tachycardia[a]
Emesis	Priapism
Lacrimation	**Nicotinic-neuromuscular neurons**
Salivation	Muscular weakness
CNS receptors (mixed type)	Cramps
Coma	Fasciculations
Seizures	Muscular paralysis

[a]Generally muscarinic effects predominate, but nicotinic effects can be observed.

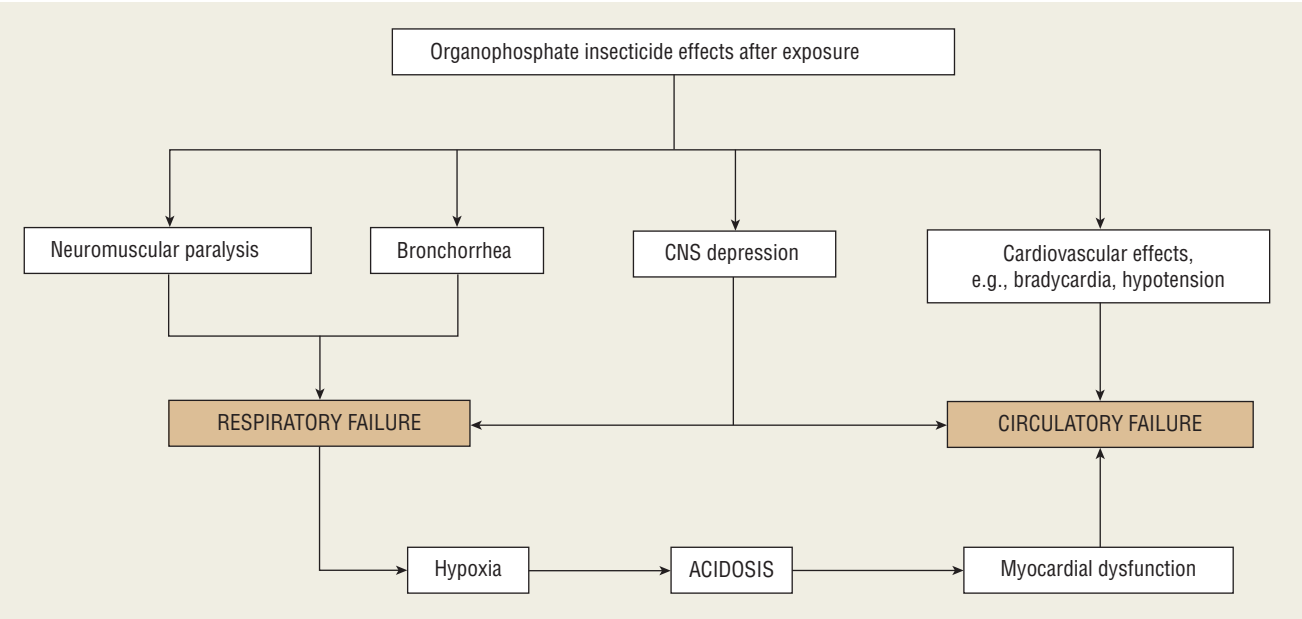

FIGURE 14-3. Pathogenesis of life-threatening effects of organophosphate poisoning. (CNS, central nervous system.)

neuropathy often presents as cramping muscle pain in the legs (upper extremities are sometimes involved), followed by rapidly progressive weakness and paralysis and develops 1 to 5 weeks after recovery from the acute poisoning exposure. Paresthesia and pain may be present. It is unresponsive to further atropine or pralidoxime therapy. Improvement may be delayed for months to years, and in some cases the patient develops permanent disability. It is not associated with all organophosphates.[74,76]

Mechanism of Toxicity

Anticholinesterase insecticides phosphorylate the active site of cholinesterase in all parts of the body.[74,77] Inhibition of this enzyme leads to accumulation of acetylcholine at affected receptors and results in widespread toxicity. Acetylcholine is the neurotransmitter responsible for physiologic transmission of nerve impulses from preganglionic and postganglionic neurons of the cholinergic (parasympathetic) nervous system, preganglionic adrenergic (sympathetic) neurons, neuromuscular junction in skeletal muscles, and multiple nerve endings in the central nervous system (Fig. 14–4).

Causative Agents

Anticholinesterase insecticides include organophosphate and carbamate insecticides. These insecticides are currently in widespread use throughout the world for eradication of insects in dwellings and crops. Carbamates typically are less potent and inactivate cholinesterase in a more reversible fashion through carbamylation compared with organophosphates.[74] The prototype anticholinesterase agent is the organophosphate, which is the focus of this discussion. A large number of organophosphates are used as pesticides (e.g., dichlorphos disulfoton, malathion, mevinphos, phosmet), and several were specifically developed for use as potent chemical warfare agents (see Chapter 16).[74,75,78,79] The chemical warfare agents act like organophosphate insecticides, but they are highly potent, are quickly absorbed, and can be deadly to humans within minutes.[79,80] An anticholinesterase insecticide typically is stored in a garage, chemical storage area, or living area. Anticholinesterase agents also can be found in occupational (e.g., pest exterminators) or agricultural (e.g., crop dusters or farm workers) settings. These agents also have been used as a means for suicide or homicide.

Incidence

Anticholinesterase insecticides are among the most poisonous substances commonly used for pest control and are a frequent source of serious poisoning in children and adults in rural and urban settings. The 2007 AAPCC-NPDS report documented 7,190 nonfatal single-product exposures and nine deaths from anticholinesterase insecticides alone or in combination with other pesticides, with 30% of exposures in children younger than 6 years.[5]

Risk Assessment

The triad of miosis, bronchial secretions, and muscle fasciculations should suggest the possibility of anticholinesterase insecticide poisoning and warrants a therapeutic trial of the antidote atropine. In cases of low-level exposure, failure to develop signs within 6 hours indicates a low likelihood of subsequent toxicity.[74] Ruling out other chemical exposures may be guided initially by symptoms at presentation.[15]

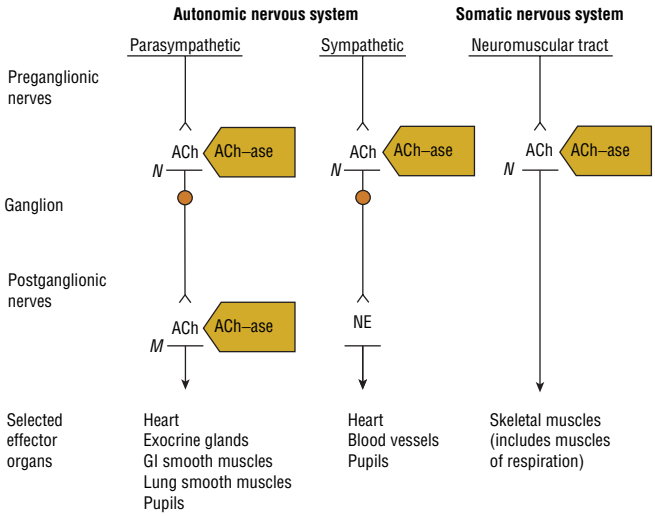

FIGURE 14-4. Organization of neurotransmitters of the peripheral nervous system and site of acetylcholinesterase action. (ACh, acetylcholine; ACh-ase, acetylcholinesterase; M, muscarinic receptor; N, nicotinic receptor; NE, norepinephrine.)

CLINICAL PRESENTATION OF ANTICHOLINESTERASE INSECTICIDE POISONING

General

- Mild symptoms may resolve spontaneously; life-threatening toxicity may develop with 1 to 6 hours of exposure

Symptoms

- Diarrhea, diaphoresis, excessive urination, miosis, blurred vision, pulmonary congestion, dyspnea, vomiting, lacrimation, salivation, and shortness of breath within 1 hour
- Headache, confusion, coma, and seizures possible within 1 to 6 hours

Signs

- Increased bronchial secretions, tachypnea, rales, and cyanosis within 1 to 6 hours
- Muscle weakness, fasciculations, and respiratory paralysis within 1 to 6 hours
- Bradycardia, atrial fibrillation, atrioventricular block, and hypotension within 1 to 6 hours

Laboratory Tests

- Markedly depressed serum pseudocholinesterase activity below normal range
- Altered arterial blood gases (acidosis), serum electrolytes, BUN, and serum creatinine in response to respiratory distress and shock within 1 to 6 hours

Other Diagnostic Tests

- Chest radiographs for progression of pulmonary edema or hydrocarbon pneumonitis in symptomatic patients
- Electrocardiogram (ECG) with continuous monitoring and pulse oximetry for complications from toxicity and hypoxia

Although the lethal dose for parathion is approximately 4 mg/kg, as little as 10 to 20 mg can be lethal to an adult and 2 mg (0.1 mg/kg) to a child. Small children may be more susceptible to toxicity because less pesticide is required per body weight to produce toxicity.[74,78] Estimation of an exact dose is impossible in most cases of acute poisoning; thus, tabulated "toxic" doses generally are not helpful in assessing risk of toxicity. Generally, ingestion of a small mouthful (~5 mL in adults) of the concentrated forms of an organophosphate intended to be diluted for commercial or agricultural use will produce serious, life-threatening toxicity, whereas a mouthful of an already diluted household product, such as an aerosol insecticide for household use, typically does not produce serious toxic effects.[78]

Measurement of acetylcholinesterase activity at the neuronal synapse is not feasible clinically. Cholinesterase activity can be measured in the blood as the pseudocholinesterase (butylcholinesterase) activity of the plasma and acetylcholinesterase activity in the erythrocyte. Both cholinesterases will be depressed with anticholinesterase insecticide poisoning.[74,78] Severity can be estimated roughly by the extent of depressed activity in relation to the low end of normal values. Because there are several methods to measure and report cholinesterase activity, each particular laboratory's normal range must be considered. Clinical toxicity usually is seen only after a 50% reduction in enzyme activity, and severe toxicity typically is observed at levels 20% or less of the normal range.[77,78] The intrinsic activity of acetylcholinesterase may be depressed in some individuals, but the absence of any manifestations in most people does not permit recognition of the relative deficiency in the general population. Therapy should not be delayed pending laboratory confirmation when insecticide poisoning is clinically suspected.

Management of Toxicity

People handling the patient should wear gloves and aprons to protect themselves against contaminated clothing, skin, or gastric fluid of the patient.[74,78] Because many insecticides are dissolved in a hydrocarbon vehicle, there is an additional risk of pulmonary aspiration of the hydrocarbon leading to pneumonitis. The risks and benefits of gastric decontamination (e.g., gastric lavage, activated charcoal) should be considered carefully and should involve consultation with a poison control center or clinical toxicologist. Symptomatic cases of anticholinesterase insecticide exposure typically are referred to an emergency department for evaluation and treatment.

If the poison has been ingested within the hour, gastric lavage should be considered and followed by the administration of activated charcoal. For the patient with skin contamination, contaminated clothing should be removed and the patient washed with copious amounts of soap and water before he or she is admitted to the emergency department or other patient care area. An alcohol wash may be useful for removing residual insecticide because of its lipophilic nature. A surgical scrub kit for the hands, feet, and nails may be useful for exposure to those areas. Supportive therapy should include maintenance of an airway (including bronchotracheal suctioning), provision of adequate ventilation, and establishment of an intravenous line. Based on a history of an exposure and presence of typical symptoms, the anticholinesterase syndrome should be recognized without difficulty.

Pharmacologic management of organophosphate intoxication relies on the administration of atropine and pralidoxime.[74,77,78] Atropine has no effect on inhibited cholinesterase, but it competitively blocks the actions of acetylcholine on cholinergic and some central nervous system receptors. It thereby alleviates bronchospasm and reduces bronchial secretions. Although atropine has little effect on the flaccid muscle paralysis or the central respiratory failure of severe poisoning, it is indicated in all symptomatic patients and can be used as a diagnostic aid. It should be given intravenously and in larger than conventional doses of 0.05 to 0.1 mg/kg in children younger than 12 years and 2 to 5 mg in adolescents and young adults.[78] It should be repeated at 5- to 10-minute intervals until bronchial secretions and pulmonary rales resolve. Therapy may require large doses over a period of several days until all absorbed organophosphate is metabolized, and acetylcholinesterase activity is restored.

Restoration of enzyme activity is necessary for severe poisoning, characterized by a reduction of cholinesterase activity to <20% of normal, profound weakness, and respiratory distress. Pralidoxime (Protopam), also called 2-PAM or 2-pyridine aldoxime methiodide, breaks the covalent bond between the cholinesterase and organophosphate and regenerates enzyme activity. Organophosphate-cholinesterase binding is reversible initially, but it gradually becomes irreversible. Therefore, therapy with pralidoxime should be initiated as soon as possible, preferably within 36 to 72 hours of exposure.[78] The drug should be given at a dose of 25 to 50 mg/kg up to 1 g intravenously over 5 to 20 minutes. If muscle weakness persists or recurs, the dose can be repeated after 1 hour and again if needed. A continuous infusion of pralidoxime has been shown to be effective in adults when administered at 2 to 4 mg/kg/h preceded by a loading dose of 4 to 5 mg/kg[81] and in children at 10 to 20 mg/kg/h with a loading dose of 15 to 50 mg/kg.[82] Both atropine and pralidoxime should be given together because they have complementary actions (Table 14–12). Systematic reviews of the literature indicate that the effectiveness of pralidoxime and similar oxime compounds in the treatment of organophosphate poisoning is inconclusive because of problems with study design.[83,84] Carbamate insecticide poisonings typically do not require the administration of pralidoxime.

One of the pitfalls of therapy is the delay in administering sufficient doses of atropine or pralidoxime.[74,78] The adverse effects of

TABLE 14-12 Comparative Characteristics of Atropine and Pralidoxime for Anticholinesterase Poisoning

Characteristic	Atropine	Pralidoxime
Interaction	Synergy with pralidoxime	Reduces atropine dose requirement
Indication	Any anticholinesterase agent	Typically needed for organophosphates
Primary sites of action	Muscarinic, CNS	Nicotinic > muscarinic > CNS
Adverse effects	Coma, hallucinations, tachycardia	Dizziness, diplopia, tachycardia, headache
Daily dose[a]	2–1,600 mg	1–12 g
Total dose[a]	2–11,422 mg	1–92 g

[a]Range of reported cases; higher doses may be required in rare cases.

atropine and pralidoxime, predictable extensions of their anticholinergic actions, are minimally important compared with the life-threatening effects of severe anticholinesterase poisoning and can be minimized easily by decreasing the dose.

CLINICAL CONTROVERSY

Some references indicate that pralidoxime should be avoided in the treatment of carbamate (another type of anticholinesterase insecticide) poisoning because of reports of worsened toxicity in animals. Pralidoxime may be considered when exposure to carbamates is not known but an anticholinesterase is suspected based on symptoms or when respiratory paralysis due to nicotinic effects is not managed sufficiently by mechanical ventilation.

Monitoring and Prevention

Poisoned patients may require monitoring of vital signs, measurement of ventilatory adequacy such as blood gases and pulse oximetry, leukocyte count with differential to assess development of pneumonia, and chest radiographs to assess the degree of pulmonary edema or development of hydrocarbon pneumonitis. Workers involved in the formulation and application of pesticides should be monitored by periodic measurement of cholinesterase activity in their bloodstream. Untreated, anticholinesterase-depressed acetylcholinesterase activity returns to normal values in approximately 120 days. Long-term follow-up for severe cases of poisoning may be necessary to detect the presence of delayed or persistent neuropsychiatric effects.

Many anticholinesterase insecticide poisonings are unintentional as a result of misuse, improper storage, failure to follow instructions for mixing or application, or inability to read directions for use. Training and vigilant adherence to directions may minimize some poisonings. Storing pesticides in original or labeled containers can minimize the risk of unintentional ingestion. Keeping pesticides out of children's reach may decrease the risk of childhood poisoning.[85]

CALCIUM CHANNEL BLOCKERS

Clinical Presentation

8 Overdosage with calcium channel blockers typically results in bradycardia and hypotension (Fig. 14–5). Many patients become lethargic and may develop agitation and coma. If the degree of hypotension becomes severe or is prolonged, the secondary effects of seizures, coma, and metabolic acidosis usually develop. Pulmonary edema, nausea and vomiting, and hyperglycemia are

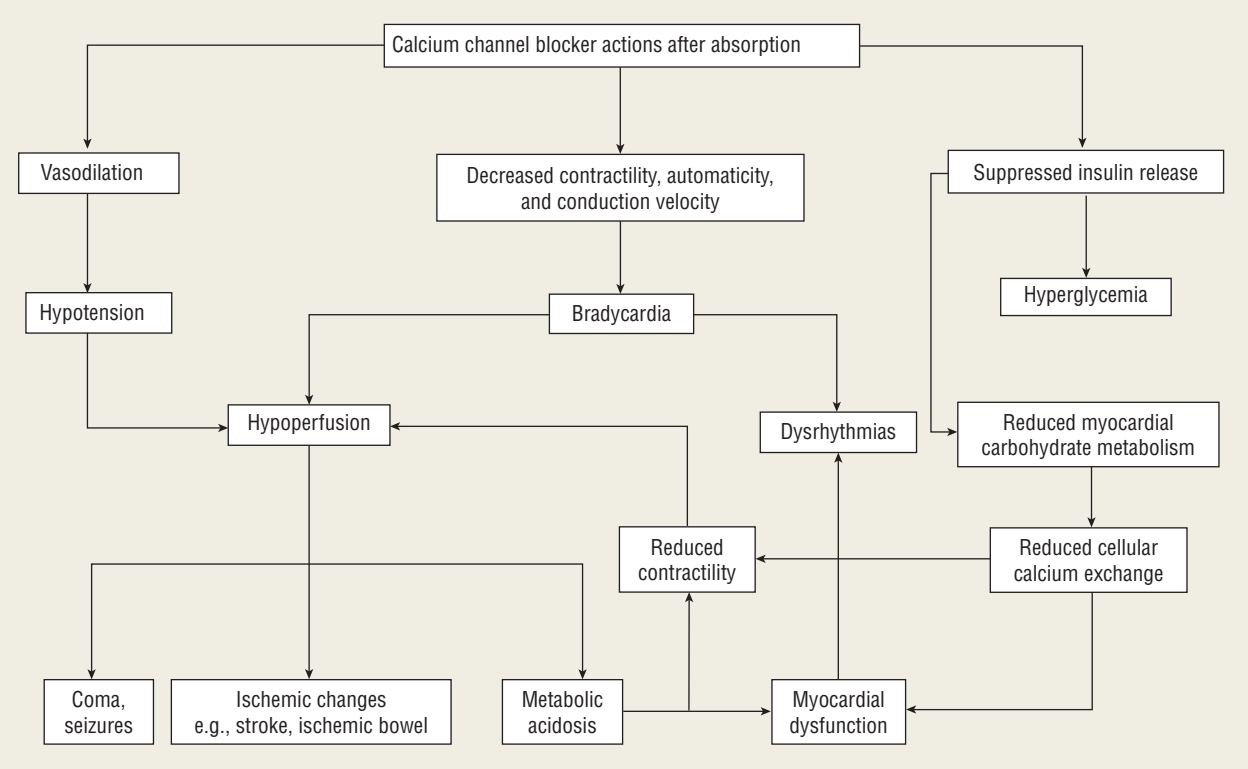

FIGURE 14-5. Pathophysiologic changes associated with calcium channel blocker poisoning.

frequent complications of calcium channel blocker overdoses. Paralytic ileus, mesenteric ischemia, and colonic infarction have been observed in patients with severe hypotension. Many symptoms become manifest within 1 to 2 hours of ingestion (see presentation box below). If a sustained-release formulation is involved, the onset of overt toxicity may be delayed by 6 to 18 hours from the time of ingestion. Severe poisoning can result in refractory shock and cardiac arrest. Death can occur within 3 to 4 hours of ingestion.[86–89]

Mechanism of Toxicity

Most toxic effects of calcium channel blockers are produced by three basic actions on the cardiovascular system: vasodilation through relaxation of smooth muscles, decreased contractility by action on cardiac tissue, and decreased automaticity and conduction velocity through slow recovery of calcium channels. Calcium channel blockers interfere with calcium entry by inhibiting one or more of the several types of calcium channels and binding at one or more cellular binding sites. Selectivity of these actions varies with the calcium channel blocker and provides some therapeutic distinctions, but these differences are less clear with overdosage.[89] Calcium channel blockers also inhibit insulin secretion, which results in hyperglycemia and changes in fatty acid oxidation in the myocardium that alter myocardial calcium flow and reduce contractility.[90] Current experiences suggest that the signs and symptoms of calcium channel blocker toxicity are similar among the drugs in this class.

CLINICAL PRESENTATION OF CALCIUM CHANNEL BLOCKER POISONING

General

- Life-threatening cardiac toxicity (bradycardia, depressed contractility, dysrhythmias) within 1 to 3 hours of ingestion, delayed by 12 to 18 hours if a sustained-release product is involved

Symptoms

- Nausea and vomiting within 1 hour
- Dizziness, lethargy, coma, and seizures within 1 to 3 hours

Signs

- Hypotension and bradycardia within 1 to 6 hours
- Unresponsiveness and depressed reflexes within 1 to 6 hours
- Atrioventricular block, intraventricular conduction defects, and ventricular dysrhythmias on ECG

Laboratory Tests

- Significant hyperglycemia (>250 mg/dL [>13.9 mmol/L]) may indicate severe toxicity and consideration for aggressive therapy
- Altered arterial blood gases (metabolic acidosis), serum electrolytes, BUN, and serum creatinine in response to shock within 1 to 6 hours

Other Diagnostic Tests

- ECG with continuous monitoring and pulse oximetry to monitor for toxicity and shock
- Monitor for complications of pulmonary aspiration such as hypoxia and pneumonia by physical findings and chest radiographs

Causative Agents

Approximately 10 calcium channel antagonists are marketed in the United States for treatment of hypertension, certain dysrhythmias, and some forms of angina. The calcium channel blockers are classified by their chemical structure (see Chapter 19) as phenylalkylamines (e.g., verapamil), benzothiapines (e.g., diltiazem), and dihydropyridines (e.g., amlodipine, felodipine, nicardipine, and nifedipine). Several of these agents, namely, diltiazem, nicardipine, nifedipine, and verapamil, are formulated as sustained-release oral dosage forms or have a slow onset of action and longer half-life (e.g., amlodipine[91]), allowing once-daily administration.

Incidence

In 2007, the AAPCC-NPDS report documented 4,759 single-product toxic exposures to a calcium channel blocker; 74 patients exhibited and survived major toxic effects, and 17 died.[5]

Risk Assessment

Ingestion of doses near or in excess of 1 g of diltiazem, nifedipine, or verapamil may result in life-threatening symptoms or death in an adult.[86] Ingestion of an amount that exceeds the usual maximum single therapeutic dose or a dose equal to or greater than the lowest reported toxic dose (whichever is less) warrants referral to a poison control center and/or an emergency department. The threshold doses of several agents and dosage forms vary (e.g., diltiazem: adults, >120 mg for immediate release and chewed sustained release, >360 mg for sustained release, >540 mg for extended release; children younger than 6 years: >1 mg/kg).[92] Patients on chronic therapy with these agents who acutely ingest an overdose may have a greater risk of serious toxicity. Elderly patients and those with underlying cardiac disease may not tolerate mild hypotension or bradycardia. Concurrent ingestion of β-adrenergic blocking drugs, digitalis, class I antiarrhythmics, and other vasodilators may worsen the cardiovascular effects of calcium channel blockers.[87,89,92] The presence of persistent and significant hyperglycemia (>250 mg/dL [13.9 mmol/L]) has been suggested as a sign of grossly disturbed cardiac metabolism and physiology that merits attention and aggressive intervention.[93]

Management of Toxicity

There is no accepted specific prehospital care for calcium channel blocker poisoning, except to summon an ambulance for symptomatic patients. Ipecac syrup should be avoided because of the risks of seizures and coma.[92] The therapeutic options for management of calcium channel blocker poisoning include supportive care, gastric decontamination, and adjunctive therapy for the cardiovascular and metabolic effects. Supportive care consists of airway protection, ventilatory support, intravenous hydration to maintain adequate urine flow, and maintenance of electrolyte and acid—base balance. Maintaining vital organ perfusion is critical for successful therapy in order to allow time for calcium channel blocker toxicity to resolve.[88,89]

Gastric lavage and a single dose of activated charcoal should be administered if instituted within 1 to 2 hours of ingestion. Besides exhibiting a slower onset of symptoms, sustained-release formulations can form concretions in the intestine.[88,89] Whole-bowel irrigation with polyethylene glycol electrolyte solution may accelerate rectal elimination of the sustained-release tablets and should be considered routinely for ingestion of sustained-release calcium channel blocker formulations.[34,94]

Adjunctive therapy is focused on treating hypotension, bradycardia, and resulting shock. Hypotension is treated primarily by correction of coexisting dysrhythmias (e.g., bradycardia, heart

block) and implementation of conventional measures to treat decreased blood pressure. Infusion of normal saline and placement of the patient in the Trendelenburg position are initial therapies. Further fluid therapy should be guided by central venous pressure monitoring. Dopamine and epinephrine in conventional doses for cardiogenic shock should be considered next. If hypotension persists, dysrhythmias are present, or other signs of serious toxicity are present, calcium should be administered intravenously.[86,89]

A calcium chloride bolus test dose (10–20 mg/kg up to 1–3 g) is the preferred therapy for patients with serious toxicity. In adults, calcium chloride 10% can be diluted in 100 mL normal saline and infused over 5 minutes through a central venous line. If a positive cardiovascular response is achieved with this test dose, a continuous infusion of calcium chloride (20–50 mg/kg/h) should be started. Calcium gluconate is less desirable to use because it contains less elemental calcium per milligram of final dosage form. Intravenous calcium salts can produce vomiting and tissue necrosis on extravasation.[52,89] Atropine also may be considered for treatment of bradycardia, but it is seldom sufficient as a sole therapy.[88]

For severe cases of calcium channel blocker toxicity refractory to conventional therapy, an infusion of high-dose insulin with supplemental dextrose and potassium to produce a state of hyperinsulinemia and euglycemia should be considered.[52,86–90] Case reports suggest that an intravenous bolus of regular insulin (0.5–1 U/kg) with 50 mL dextrose 50% (0.25 mg/kg for children) followed by a continuous infusion of regular insulin (0.5 to 1 U/kg/h) may improve myocardial contractility. The effect of insulin is presently unclear, but it may improve myocardial metabolism that is adversely affected by calcium channel blocker overdoses, such as decreased cellular uptake of glucose and free fatty acids and a shift from fatty acid oxidation to carbohydrate metabolism.[86,88,90] This insulin regimen is titrated to improvement in systolic blood pressure over 100 mm Hg and heart rate over 50 beats/min. Serum glucose concentrations should be monitored closely to maintain euglycemia. Patients with serum potassium concentrations <2.5 mEq/L (<2.5 mmol/L) may need supplemental potassium (see Chapter 60). The insulin infusion rate can be reduced gradually as signs of toxicity resolve. Intravenous sodium bicarbonate may be also necessary to establish acid—base balance and correct the metabolic acidosis that is common with serious calcium channel blocker overdoses.

If the bradycardia and hypotension are refractory to the foregoing therapy, a bolus infusion of glucagon (0.05–0.20 mg/kg, initial adult dose is 3–5 mg over 1–2 min) should be considered. Benefit typically is observed within 5 minutes of administration and can be sustained with a continuous intravenous infusion (0.05–0.1 mg/kg/h) titrated to clinical response.[95] Glucagon possesses chronotropic and inotropic effects in part by stimulating adenylate cyclase and increasing cyclic adenosine monophosphate, which may promote intracellular entry of calcium through calcium channels. It thereby may improve hypotension and bradycardia.[52] Vomiting is not uncommon with these large doses of glucagon, and the airway should be protected to prevent pulmonary aspiration. Hyperglycemia may occur or be exacerbated in those patients receiving glucagon therapy.

Therapies with glucagon and insulin are based on animal studies and case reports; clinical trials demonstrating effectiveness have not been performed to date.[52,86–90]

Several lifesaving options may be warranted for patients with cardiogenic shock that is refractory to conventional therapy. Electrical cardiac pacing may restore an acceptable heart rate in patients with severe bradycardia.[89] Intraaortic balloon counterpulsation or cardiopulmonary bypass may improve shock in patients unresponsive to other therapies.[52,89,96,97] Animal studies and cases from the anesthesiology literature suggest that the emergent infusion of lipid emulsion, e.g., Intralipid, can dramatically "rescue" patients with severe cardiac toxicity from lipid soluble drugs such as calcium channel blockers. Some current hypotheses on the actions responsible for this effect include serving as a "lipid sink" for lipophillic drugs and as an energy substrate for the myocardium. There are several dosing schemes and none are well studied to date. Better and more evidence is needed to know if it has a place in therapy.[54,98]

Measures to enhance elimination from the bloodstream by hemodialysis or multiple-dose activated charcoal have not been shown to be effective and are not indicated for calcium channel blocker poisoning.[42,87,89,99]

CLINICAL CONTROVERSY

Some clinicians believe that hyperinsulinemia/euglycemia or glucagon therapy for calcium channel blocker poisoning should be used early in the course of therapy. Others reserve it for life-threatening symptoms not responsive to other therapy. More safety and effectiveness data are needed to define the place of these two agents in therapy.

Monitoring and Prevention

Regular monitoring of vital signs and ECG is essential in suspected calcium channel blocker poisoning. Determinations of serum electrolytes, serum glucose, arterial blood gases, urine output, and renal function are indicated to assess and monitor symptomatic patients. If serious toxicity is likely to develop, overt symptoms will manifest within 6 hours of ingestion.[92] For ingestions of sustained-release products in toxic doses, observation for 24 hours in a critical care unit may be prudent because the onset of symptoms may be slow and delayed up to 12 to 18 hours after ingestion.[86,92,94,99,100] Serum concentrations of these agents in overdose patients do not correlate well with the ingested dose, degree of toxicity, or outcome.

Poisonings resulting from these agents may be the result of an intentional suicide or unintentional ingestion by young children. Prevention of calcium channel blocker poisonings in children rests with the education of patients receiving these agents, particularly of grandparents and those who have children visit their homes infrequently, of their dangers on overdosage. Safe storage and use of child-resistant closures may reduce the opportunities for unintentional poisonings by children.[87]

IRON

Clinical Presentation

9 In the first few hours after ingestion of toxic amounts of iron, symptoms of gastrointestinal irritation (e.g., nausea, vomiting, and diarrhea) are common (see presentation box below). In certain severe cases, acidosis and shock can become manifest within 6 hours of ingestion. Some have observed a quiescent phase between 6 and 48 hours after ingestion when symptoms improve or abate, but this phenomenon is poorly characterized.[101] Continued gastrointestinal symptoms, poor perfusion, and oliguria should suggest the development of severe toxicity, with other effects still to become manifest. Generally, within 24 to 36 hours of the ingestion, central nervous system involvement with coma and seizures; hepatic injury characterized by jaundice, increased INR, increased bilirubin, and hypoglycemia; cardiovascular shock; and acidosis also develop.[101,102] Adult respiratory distress syndrome (ARDS) may develop in patients with severe cardiovascular shock and further compromise recovery.[103] Coagulopathy with decreased thrombin formation is one of the early direct effects of excessive

iron concentrations, and later disturbances of coagulation (after 24 to 48 hours of ingestion) are a consequence of hepatotoxicity.[104] Mucosal injury, an iron-rich circulation, or deferoxamine therapy may promote septicemia with *Yersinia enterocolitica* during iron overdose; other bacteria or viruses also may cause septicemia.[101] Two to 4 weeks after the exposure, a small percentage of patients experience persistent vomiting from gastric outlet obstruction as the result of pyloric and duodenal stenosis from the earlier gastric mucosal necrosis. Autopsy findings in children indicate prominent iron deposition in intestinal mucosa and periportal necrosis of the liver that correlate with the primary symptoms of serious iron poisoning.[105]

Mechanism of Toxicity

The toxicity of acute iron poisoning includes local effects on the gastrointestinal mucosa and systemic effects induced by excessive iron in the body.[101,103] Iron is irritating to the gastric and duodenal mucosa, which may result in hemorrhage and occasional perforations. Once absorbed, iron is taken up by tissues, particularly the liver, and acts as a mitochondrial poison. It occasionally causes hepatic injury. Iron may inhibit aerobic glycolysis and perturb the electron transport system. Further, iron may shunt electrons away from the electron transport system, thereby reducing the efficiency of oxidative phosphorylation. These biochemical factors, along with the cardiovascular effects of iron, lead to metabolic acidosis. The pathogenesis of shock is not well understood but may include the development of hypovolemia and lactic acidosis, release of endogenous vasodilators, and the direct vasodepressant effects of iron and ferritin on the circulation (Fig. 14–6).

Causative Agents

Iron poisoning results from the ingestion and absorption of excessive amounts of iron from iron tablets, multiple vitamins with iron, and prenatal vitamins. Different iron salts and formulations contain varying amounts of elemental iron (see Chapter 109). Generally, children's chewable vitamins are less likely to produce systemic iron poisoning in part because of their lower iron content.[106]

Incidence

Acute iron poisoning can produce death in children and adults.[105,106] The 2007 AAPCC-NPDS report documented 3,196 single-agent iron ingestions, with 3.1% of the exposures exhibiting moderate to severe toxicity. Children younger than 6 years accounted for 60% of the exposures. Multiple vitamins with iron were involved in 23,535 cases, with 0.2% exhibiting moderate-severe toxicity. No deaths were associated with any iron product during this year.[5]

CLINICAL PRESENTATION OF ACUTE IRON POISONING

General

- Gastrointestinal symptoms shortly after ingestion with possible rapid progression to shock and coma

Symptoms

- Vomiting, abdominal pain, and diarrhea within 1 to 6 hours
- Lethargy, coma, seizures, bloody vomiting, bloody diarrhea, and shock within 6 to 24 hours

Signs

- Hypotension and tachycardia within 6 to 24 hours
- Liver dysfunction and failure possible in 2 to 5 days

Laboratory Tests

- Toxic serum iron concentrations >500 mcg/dL (>90 mmol/L)
- Altered arterial blood gases and serum electrolytes associated with a high anion gap metabolic acidosis within 3 to 24 hours
- Elevated BUN, serum creatinine, AST, ALT, and INR within 1 to 2 days

Other Diagnostic Tests

- Guaiac test of stools for the presence of blood
- Abdominal radiograph to detect solid iron tablets in gastrointestinal tract

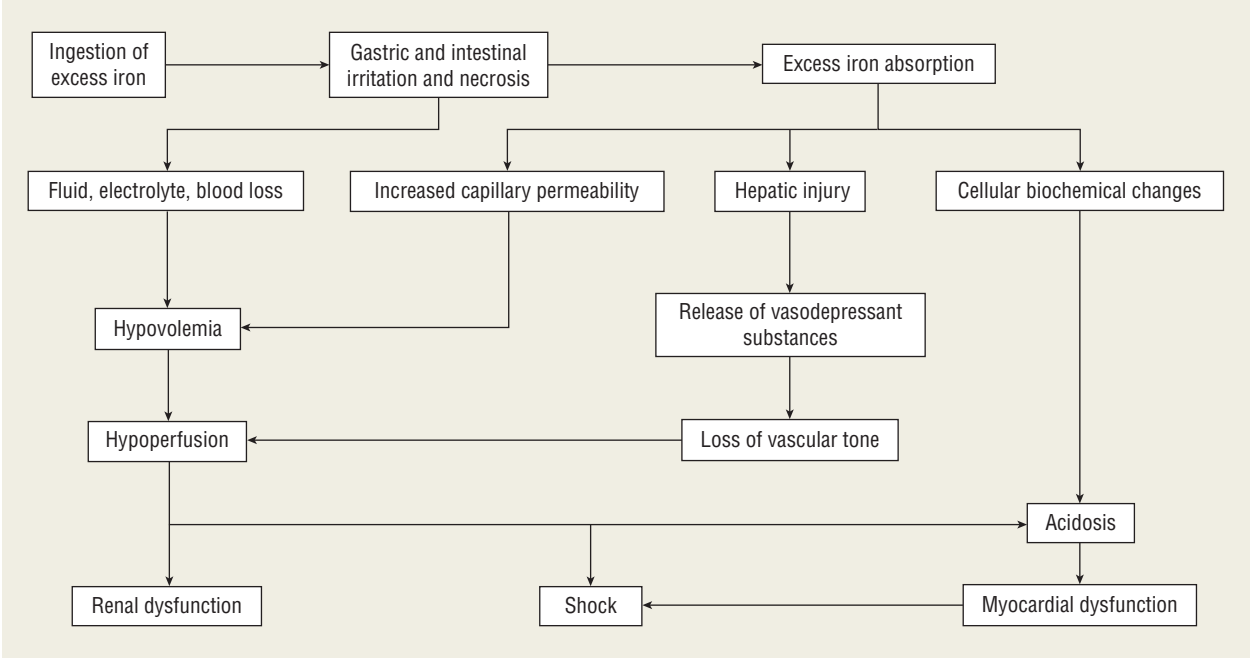

FIGURE 14-6. Pathophysiology of acute iron poisoning.

Risk Assessment

A patient who exhibits lethargy, paleness, persistent or bloody emesis, or diarrhea should be immediately referred to an emergency department.[106] Ingestion of 10 to 20 mg/kg elemental iron usually elicits mild gastrointestinal symptoms. Ingestion of 20 to 40 mg/kg is not likely to produce systemic toxicity, and typically these patients can be conservatively managed at home. Ingestions of 40 mg/kg or more of elemental iron are often associated with serious toxicity and require immediate medical attention.[106] Psychiatric as well as medical intervention is indicated for adults and adolescents who intentionally ingest iron as a suicide gesture.[101,103,106]

An abdominal radiograph may help to confirm the ingestion of iron tablets and indicate the need for aggressive gastrointestinal evacuation with whole-bowel irrigation. An abdominal radiograph is most useful within 2 hours of ingestion. The visualization of radiopaque iron tablets is confounded by the presence of other hard-coated tablets and some extended-release tablets that also are radiopaque. Furthermore, the radiopacity of iron tablets diminishes as the tablets disintegrate, and chewable and liquid formulations typically are not radiopaque.[107]

Iron poisoning causes vomiting and diarrhea, but these symptoms are poor indicators of later serious toxicity. The presence of a combination of findings such as coma, radiopacities, leukocytosis, and increased anion gap, however, is associated with dangerously high serum concentrations >500 mcg/dL (>90 mmol/L). The presence of single signs and symptoms, such as vomiting, leukocytosis, or hyperglycemia, is not a reliable indicator of the severity of iron poisoning in adults or children.[108,109]

Once iron is absorbed, it is eliminated only as the result of blood loss or sloughing of the intestinal and epidermal cells. Thus, iron kinetics essentially represent a closed system with multiple compartments. The serum iron concentration represents a small fraction of the total-body content of iron and is at its greatest concentration in the postabsorptive and distributive phases, typically 2 to 10 hours after ingestion.[110] Serum iron concentrations >500 mcg/dL (>90 mmol/L) have been associated with severe toxicity, whereas concentrations <350 mcg/dL (<62.7 mmol/L) typically are not associated with severe toxicity; however, exceptions have been reported for both thresholds.[110] Serious toxicity is best determined by assessing the development of gross gastrointestinal bleeding, metabolic acidosis, shock, and coma regardless of the serum iron concentration.[103] The serum iron concentration serves as a guide for further assessment and treatment options. The ratio of the serum iron concentration to the total iron-binding capacity is unreliable, insensitive, and has little relationship to acute toxicity.[109]

Management of Toxicity

Many patients vomit spontaneously, and ipecac syrup should be avoided.[106] At the emergency department, gastric lavage with normal saline can be considered. Lavage with normal saline may remove iron tablet fragments and dissolved iron, but because the lumen of the tube is often smaller than some whole tablets, effective removal is unlikely.[101] Activated charcoal administration is not warranted routinely because it adsorbs iron poorly. If abdominal radiographs reveal a large number of iron tablets, whole-bowel irrigation with polyethylene glycol electrolyte solution typically is necessary.[34] Although removal by gastrostomy has been used in a few cases,[103] early and aggressive decontamination and evacuation of the gastrointestinal tract usually will be adequate to minimize iron absorption and thereby reduce the risk of systemic toxicity. Lavage solutions of phosphate or deferoxamine have been proposed previously as a means to render iron insoluble, but they were found ineffective and dangerous.[103,106]

Patients with systemic symptoms (e.g., shock, coma, or gross gastrointestinal bleeding or metabolic acidosis) should receive parenteral deferoxamine as soon as possible. If the serum iron concentration is >500 mcg/dL (>90 mmol/L), deferoxamine is also indicated because serious systemic toxicity is likely.[101,103] Its use is less clear in patients with serum iron concentrations in the range from 350 to 500 mcg/dL (62.7–90 mmol/L) because many of these patients do not develop systemic symptoms.[110]

Deferoxamine is a highly selective chelator of iron that theoretically binds ferric (Fe^{3+}) iron in a 1:1 molar ratio (100 mg deferoxamine to 8.5 mg ferric iron) that is more stable than the binding of iron to transferrin. Deferoxamine removes excess iron from the circulation and some iron from transferrin by chelating ferric complexes in equilibrium with transferrin. The resulting iron—deferoxamine complex, ferrioxamine, is then excreted in the urine. Its action on intracellular iron is unclear, but it may have a protective intracellular effect or may chelate extramitochondrial iron.[103] The parenteral administration of deferoxamine produces an orange—red-colored urine within 3 to 6 hours because of the presence of ferrioxamine in the urine.[101] For mild-to-moderate cases of iron poisoning, where its use is unclear, the presence of discolored urine indicates the persistent presence of chelatable iron and the need to continue deferoxamine. The reliance on discolored urine as a therapeutic end point has been challenged because it is not sensitive and is difficult to detect.[111]

An initial intravenous infusion of 15 mg/kg/h generally is indicated, although some have used up to 30 mg/kg/h for life-threatening cases. In these situations, the dose must be titrated carefully to minimize deferoxamine-induced hypotension.[101,103,112] The rapid intravenous infusion of deferoxamine (>15 mg/kg/h) has been associated with tachycardia, hypotension, shock, generalized erythema, and urticaria.[101,113] Anaphylaxis has been reported rarely. The use of deferoxamine for more than 24 hours at doses used for treatment of acute poisoning has been associated with exacerbation or development of ARDS.[113–115] Although the manufacturer states that the total dose in 24 hours should not exceed 6 g, the basis for this recommendation is unclear, and daily doses as high as 37.1 g have been administered without incident.[112,114] Good hydration and urine output may moderate some of the secondary physiologic effects of iron toxicity and ensure urinary elimination of ferrioxamine. In the patient who develops renal failure, hemodialysis or hemofiltration does not remove excess iron but will remove ferrioxamine.[101]

The desired end point for deferoxamine therapy is not clear. Some have suggested that deferoxamine therapy should cease when the serum iron concentration falls below 150 mcg/dL (26.9 mmol/L).[103] The decline of serum iron concentrations, however, may not account for the potential cellular action of deferoxamine irrespective of its effect on iron elimination. The cessation of orange-red urine production that is indicative of ferrioxamine excretion is not reliable because many individuals cannot distinguish its presence in the urine.[111] Considering these shortcomings, deferoxamine therapy should be continued for 12 hours after the patient is asymptomatic and the urine returns to normal color or until the serum iron concentration falls below 350 mcg/dL (62.7 mmol/L) and approaches 150 mcg/dL (26.9 mmol/L).

CLINICAL CONTROVERSY

There is little evidence on how much deferoxamine should be given for iron poisoning or for how long it should be administered. The dosage regimen should balance the benefits of increased iron removal in patients with exceedingly high serum iron concentrations versus the risk of developing ARDS when therapy lasts for more than 1 to 3 days.

Monitoring and Prevention

Once a poisoning has occurred, acid—base balance (anion gap and arterial blood gases), fluid and electrolyte balance, and perfusion should be monitored. Other indicators of organ toxicity, such as

ALT, AST, bilirubin, INR, serum glucose and creatinine concentrations, as well as markers of physiologic stress or infection such as leukocytosis, also should be monitored.

Iron poisoning often is not recognized as a potentially serious problem by parents or victims until symptoms develop; thus, valuable time to institute treatment is lost. Parents should be made aware of the potential risks and asked to observe basic poison prevention measures. Some hard-coated iron tablets resemble candy-coated chocolates and are confused easily by children. Based on these considerations and the frequency of this poisoning, iron tablets are packaged in child-resistant containers.

TRICYCLIC ANTIDEPRESSANTS

Clinical Presentation

⑩ Patients may deteriorate rapidly and progress from no symptoms to life-threatening cardiotoxicity or seizures within 1 hour.[116,117] Major symptoms of tricyclic antidepressant overdose typically are manifest within 6 hours of ingestion.[116] The principal effects of tricyclic antidepressant poisoning involve the cardiovascular system and the central nervous system and can result in arrhythmias, hypotension, coma, and seizures (see presentation box below).

Prolongation of the QRS complex on ECG indicating nonspecific intraventricular conduction delay or bundle-branch block is the most distinctive feature of tricyclic antidepressant overdose.[117] Sinus tachycardia with rates typically <160 beats/min is common and does not cause serious hemodynamic changes in most patients. Ventricular tachycardia is a common ventricular arrhythmia, but it may be difficult to distinguish from sinus tachycardia in the presence of QRS complex prolongation and the apparent absence of P waves. It often occurs in patients with marked QRS complex prolongation or hypotension and may be precipitated by seizures.[117,118] High rates of mortality are associated with ventricular tachycardia; ventricular fibrillation is the terminal rhythm. Torsade de pointes is observed infrequently with tricyclic antidepressant poisoning. With massive tricyclic antidepressant overdose, slow ventricular rhythms may be observed. Hypotension is a significant factor in most cases of tricyclic antidepressant poisoning. Refractory hypotension leading to death is due to vasodilation and impaired cardiac contractility.[117] Other factors, such as extreme heart rates, intravascular volume depletion, hypoxia, hyperthermia, seizures, and acidosis, may contribute to refractory hypotension.

Coma usually is present in patients with tricyclic antidepressant poisoning and may or may not be associated with QRS complex prolongation. In severe cases, coma is sufficient to depress respirations. Delirium, manifest as agitation or disorientation, may occur early in the course of severe poisoning or with poisoning of moderate severity. Seizures often occur within 2 hours of ingestion and usually are generalized, single, and brief. Seizures may result in acidosis, hyperthermia, or rhabdomyolysis, and 10% to 20% of patients may abruptly develop cardiovascular deterioration.[117] Myoclonus also may be observed with tricyclic antidepressant overdose. Hyperthermia often results from seizure and myoclonic activity in the presence of decreased sweating and is associated with a high incidence of neurologic sequelae and mortality. Anticholinergic symptoms, such as urinary retention, ileus, and dry mucous membranes, often are observed with tricyclic antidepressant overdose.[116,117] Pupil size is variable.

Tricyclic antidepressant overdose can be staged based on the patient's symptoms and recovery time. In stage 1, patients are responsive to pain, have sinus tachycardia, and recover within 24 hours. In stage 2, seizures, coma, and cardiac conduction problems are evident; respiratory support typically is needed. Patients recover within 24 to 48 hours of ingestion. Stage 3 is characterized by the features of stage 2 with the addition of respiratory arrest, hypotension, ventricular dysrhythmias, and asystole, which may occur within 1 to 24 hours of ingestion. Typically symptoms appear within 2 hours, and more serious effects usually are not seen until 6 hours postingestion; rarely rapid clinical deterioration is observed within 1 to 2 hours.[119]

Amoxapine, bupropion, and maprotiline are atypical antidepressants associated with a higher incidence of seizures on overdose; amoxapine produces minimal cardiotoxicity,[117,120] but venlafaxine has been associated with greater mortality.[121] The selective serotonin reuptake inhibitors (SSRIs) generally produce a common toxicity profile on overdose despite their structural and pharmacologic distinctions.[122] The SSRIs inhibit presynaptic neuronal uptake of serotonin, resulting in increased synaptic serotonin levels. When ingested in excess, SSRIs rarely cause death and typically produce nausea, vomiting, diarrhea, tremor, and decreased level of consciousness.[122] Tachycardia and seizures are infrequent.[117,120,123]

Serotonin syndrome is a condition in which certain drugs (e.g., meperidine, nonselective monoamine oxidase inhibitors, dextromethorphan, linezolid, tricyclic antidepressants, SSRIs) acutely increase serotonin levels and develops within minutes to hours (typically within 6 hours) after starting a medication, increasing the dose of a medication, or overdosing. It is characterized by a collection of neurobehavioral (e.g., confusion, agitation, coma, seizures), autonomic (e.g., hyperthermia, diaphoresis, tachycardia, hypertension), and neuromuscular (e.g., myoclonus, rigidity, tremor, ataxia, shivering, nystagmus) signs and symptoms.[124] Most cases are mild and resolve spontaneously within 24 to 72 hours. Cardiac arrest, coma, and multiorgan system failure have been reported as consequences of serotonin syndrome.[124] Recognition of the syndrome is based on a high index of suspicion and identification of risk factors.

CLINICAL PRESENTATION OF TRICYCLIC ANTIDEPRESSANT POISONING

General

- Sedating and cardiovascular effects observed within 1 hour of ingestion, quickly leading to life-threatening symptoms; death is possible within 1 to 2 hours

Symptoms

- Lethargy, coma, and seizures occur within 1 to 6 hours
- Dry mouth, mydriasis, urinary retention, and hypoactive bowel sounds, develop within 1 to 6 hours

Signs

- Tachycardia within 1 to 3 hours
- Mild hypertension early will change to severe hypotension and shock within 1 to 6 hours
- Unresponsiveness and depressed reflexes within 1 to 3 hours
- Depressed respiratory rate and depth depending on the degree of coma
- Common arrhythmias, such as prolonged QRS and QT intervals to ventricular dysrhythmias, within 1 to 6 hours

Laboratory Tests

- Altered arterial blood gases associated with metabolic acidosis from hypoxia and seizures
- Altered serum electrolytes, BUN, and serum creatinine in response to seizures and shock within 3 to 12 hours

Other Diagnostic Tests

- ECG with continuous monitoring and pulse oximetry to monitor for toxicity and shock
- Monitor for complications of pulmonary aspiration, such as hypoxia and pneumonia, by physical findings and chest radiograph

Mechanism of Toxicity

Many of the toxic effects of tricyclic antidepressants are associated with an exaggeration of their pharmacologic action. The tricyclic antidepressants, such as type Ia antiarrhythmic drugs, inhibit the fast sodium channel so that phase 0 depolarization of the myocardium is slowed.[117] This action leads to QRS complex prolongation, atrioventricular block, ventricular tachycardia, and decreased myocardial contractility. Tricyclic antidepressants also block vascular *a*-adrenergic receptors, resulting in vasodilation, which contributes to hypotension. Sinus tachycardia is related to the inhibition of norepinephrine reuptake and anticholinergic effects. Other anticholinergic effects include urinary retention, ileus, dry mucous membranes, and impaired sweating. Inhibition of norepinephrine reuptake also may account for the early, transient, and self-limiting elevation of blood pressure observed in some patients. The central nervous system toxicity of tricyclic antidepressants is not well understood.

Causative Agents

Tricyclic antidepressants and SSRIs are used to treat a variety of behavioral conditions (see Chapters 77–79). The tricyclic antidepressants include drugs such as amitriptyline, desipramine, doxepin, imipramine, and nortriptyline. Atypical agents include amoxapine, bupropion, maprotiline, nefazodone, trazodone, and venlafaxine. The SSRIs include fluoxetine, paroxetine, and sertraline. The tricyclic antidepressants are generally highly protein bound, exhibit a large volume of distribution, and possess elimination half-lives of 8 to 24 hours or more. Virtually none of the drug is eliminated unchanged in the urine. Metabolism of the parent drug produces active metabolites in most cases (e.g., amitriptyline to nortriptyline) that may contribute to toxicity after the first 12 to 24 hours.[117] Genetic polymorphism at *CYP2D6* may lead to slower recovery in patients who are slow hydroxylators.[125]

Incidence

Tricyclic antidepressant poisoning is a common cause of death from drug overdose.[117,118] The 2007 AAPCC-NPDS report documented 43,198 patients with single-agent exposures to tricyclic antidepressants; 42% of these cases were considered to be intentional overdoses. A total of 922 people experienced a major effect, and 32 people died.[5] The SSRIs accounted for 19,407 nonfatal single-agent exposures with 84 people exhibiting severe toxicity but no deaths were reported this year.

Risk Assessment

Referral to an emergency department is warranted for ingestions >5 mg/kg of amitriptyline, clomipramine, doxepin, and imipramine; >2.5 mg/kg of desipramine, nortriptyline, and trimipramine; and >1 mg/kg of protriptyline.[119] Patients who exhibit weakness, drowsiness, dizziness, tremulousness, and palpitations after an ingestion of a tricyclic antidepressant and patients suspected of a suicide gesture or those who are suspected victims of malicious poisoning should be promptly referred to an emergency department.[119] A QRS complex >160 milliseconds or progressive prolongation of the QRS complex is an indicator of toxicity such as seizures or ventricular arrhythmias and often precedes the onset of serious symptoms.[116,118,126] The QRS complex duration should not be used as the sole indicator of risk for tricyclic antidepressant poisoning.[126] Although urine drug analyses routinely screen for tricyclic antidepressants, the qualitative result can only suggest or confirm a potential risk for the development of toxicity.

Patients with coexisting cardiovascular and pulmonary conditions (e.g., ARDS, pulmonary infection, pulmonary aspiration) may be more susceptible to the toxic effects or complications of tricyclic antidepressant poisoning.[119] Tricyclic antidepressants interact with other central nervous system depressant drugs, which together may lead to increased central nervous system and respiratory depression.

Consult a poison control center for current recommendations for doses of SSRIs that would warrant referral to an emergency department.[127] The risk of serotonin syndrome may be increased shortly after dosage increases of SSRIs or when drug interactions increase serotonin activity.[124] Concomitant or proximal use of SSRIs, tricyclic antidepressants, or nonselective monoamine oxidase inhibitors may cause serotonin syndrome. Furthermore, the addition of certain drugs, such as tryptophan, dextromethorphan, cocaine, or sympathomimetics, to SSRI therapy may increase the risk of developing serotonin syndrome.[124]

Management of Toxicity

Once the ingestion of an overdose of tricyclic antidepressant is suspected or for any intentional ingestions, medical evaluation and treatment should be sought promptly. If the patient is symptomatic, it may be prudent to call for an ambulance because of the rapid progression of some cases. At the emergency department, the patient should be monitored carefully, have vital signs assessed regularly, and have an intravenous line started. Supportive and symptomatic care includes oxygen, intravenous fluids, and other treatments as indicated. Prompt administration of activated charcoal may decrease the absorption of any remaining tricyclic antidepressant. It also may be useful beyond the first hour of ingestion because of decreased gastrointestinal motility from the anticholinergic action of tricyclic antidepressants. Gastric lavage may be considered if the time of the ingestion is unknown or if ingestion occurred within the past 1 to 2 hours. Some practitioners avoid gastric lavage altogether.[117] Ipecac syrup should be avoided in patients who ingest tricyclic antidepressants because the rapid onset of toxicity compromises its safety. Multiple-dose activated charcoal has been shown to increase the elimination of some tricyclic antidepressants in human volunteers[42] and has been used in poisoned patients.[116,117] It may be most useful during the first 12 hours of ingestion while the drug is distributing to tissue compartments. Because the tricyclic antidepressants possess a large volume of distribution, little of the drug is present in the bloodstream; thus hemodialysis is not useful for the extracorporeal removal of tricyclic antidepressants.

Intravenous sodium bicarbonate is part of the first-line treatment of QRS complex prolongation, ventricular arrhythmias, and hypotension caused by tricyclic antidepressant overdose.[52,117,128] Typically 1 to 2 mEq/kg (1–2 mmol/kg) sodium bicarbonate (1 mEq/mL [1 mmol/mL]) is administered as a bolus infusion (usually a 50-mEq [50-mmol] ampule in an adult) and repeated as necessary to achieve an arterial blood pH of 7.50 to 7.55 or abatement of toxicity.[116,117] A therapeutic effect usually is observed within minutes. Excessive use of sodium bicarbonate may produce dangerous alkalemia, which by itself is associated with ventricular arrhythmias.[117] The mechanism of action of sodium bicarbonate is unclear. Although some practitioners have proposed that sodium bicarbonate increases protein binding of tricyclic antidepressants, this theory has been discounted. Sodium may play an important role by stabilizing tricyclic antidepressant—induced changes to the sodium gradient of the myocardium.[117,129] Regardless of its action, it is effective and generally safe. Hyperventilation to produce a mild state of respiratory alkalosis has been used to treat some dysrhythmias, but it is used less widely than sodium bicarbonate.[116,117]

CLINICAL CONTROVERSY

Because intravenous sodium bicarbonate is used as therapy for certain arrhythmias and hypotension caused by tricyclic antidepressant poisoning, some practitioners have advocated its prophylactic use. Little evidence indicates which patients would benefit from prophylactic use. The risks of potentially producing alkalosis in a patient who is not seriously toxic should be considered.

Treatment of the complications of tricyclic antidepressant poisoning is outlined in Table 14–13 and includes pharmacologic and nonpharmacologic approaches.[116,117] Several agents generally should be avoided in the treatment of tricyclic antidepressant poisoning. Other drugs that inhibit the fast sodium channel, such as procainamide and quinidine, are contraindicated. Phenytoin has limited usefulness in treating tricyclic antidepressant seizures and has questionable efficacy in managing cardiotoxicity.[116] Physostigmine was used in the past as a treatment of tricyclic antidepressant-induced cardiotoxicity and seizures because it antagonizes anticholinergic actions. However, physostigmine has been associated with bradycardia and asystole[117,130] and has been avoided in the contemporary treatment of tricyclic antidepressant cardiovascular or central nervous system toxicity. Flumazenil is used to antagonize the effects of benzodiazepines, but its use in the presence of a tricyclic antidepressant has been associated with the development of seizures and should be avoided.[131]

Treatment of an overdose of the atypical antidepressants and SSRIs is directed primarily toward decontamination of the gastrointestinal tract with activated charcoal, symptomatic treatment, and general supportive care. Management of the serotonin syndrome involves discontinuation of the serotoninergic agent and supportive therapy. Benzodiazepines, propranolol, and cyproheptadine, a serotonin antagonist, have been used successfully.[124]

TABLE 14-13 Treatment Options for Acute Tricyclic Antidepressant Toxicity

Toxicity	Treatment
Cardiovascular	
QRS prolongation, if progressive or >0.16 s	Intravenous sodium bicarbonate to a blood pH of 7.5 even in the absence of acidosis; generally avoid other antiarrhythmic drugs
Hypotension	Intravascular fluids; intravenous sodium bicarbonate; consider norepinephrine or dopamine
Ventricular tachycardia	Intravenous sodium bicarbonate; lidocaine, overdrive pacing
Ventricular bradycardia	Epinephrine drip; cardiac pacemaker
Atrioventricular block type II, second or third degree	Cardiac pacemaker
Cardiac arrest	Advanced cardiac life support, prolonged resuscitation may be needed
Neurologic	
Seizures, agitation	Benzodiazepines; neuromuscular blockade may be needed if hyperthermia or acidosis is present
Coma	Endotracheal intubation; mechanical ventilation if needed
Homeostatic	
Hyperthermia	Treat seizures and agitation; consider cooling blanket, ice water lavage, and cool water mist of body
Acidosis	Intravenous sodium bicarbonate

Monitoring and Prevention

Measurement of vital signs, electrolytes, and BUN and a urinalysis are indicated for initial assessment. Patients should be monitored continuously by ECG, and a 12-lead ECG should be obtained if QRS complex prolongation is noted. If patients start to show signs of cardiotoxicity, arterial blood gases should be determined. Patients who show no signs of toxicity during 6 hours of observation and have received activated charcoal promptly require no further medical monitoring. Psychiatric evaluation is indicated for adolescents and adults. When signs of tricyclic antidepressant toxicity are present in a patient, cardiac monitoring generally is recommended for at least 24 hours after the patient is without findings.[117]

Prevention of tricyclic antidepressant poisoning poses unique challenges. Many of the dosage forms are small in size, and adults and children can consume large numbers easily. In the course of treating depression, several antidepressant agents may be tried to achieve results. By not discarding unused medicines, a storehouse of potentially deadly drugs may be available for children to discover or for the despondent patient to use to attempt suicide. Although patients take tricyclic antidepressants for therapeutic relief of depression, they are also a group likely to contemplate suicide with tricyclic antidepressants. Strategies that would limit the amount of tricyclic antidepressant prescribed at one time also potentially would impair adherence to a dosage regimen and thereby compromise the therapeutic potential of these agents.[117,128] Patients with a history of suicidal gestures may be candidates for the atypical antidepressants or SSRIs, which possess less cardiotoxicity. General poison prevention measures may limit childhood poisonings; and monitoring depressed patients for suicidal ideation may identify patients at risk.[132]

ABBREVIATIONS

AAPCC-NPDS: American Association of Poison Control Centers' National Poison Data System

ALT: alanine aminotransferase

ARDS: adult respiratory distress syndrome

AST: aspartate aminotransferase

BUN: blood urea nitrogen

ECG: electrocardiogram

INR: international normalized ratio

NAPQI: *N*-acetyl-*p*-benzoquinoneimine

PPPA: Poison Prevention Packaging Act (of 1970)

CHAPTER 15

Emergency Preparedness: Identification and Management of Biologic Exposures

COLLEEN M. TERRIFF, JASON E. BROUILLARD, LISA T. COSTANIGRO, AND JESSICA S. OFTEBRO

KEY CONCEPTS

1. Bioterrorism agents are organisms or toxins that can cause disease and death in humans, animals, or plants and elicit terror.
2. Category A bioterrorism agents include anthrax (*Bacillus anthracis*), tularemia (*Francisella tularensis*), smallpox (*variola major*), plague (*Yersinia pestis*), botulinum toxin (*Clostridium botulinum*), and viral hemorrhagic fevers.
3. An important therapeutic concept surrounding prophylaxis involves prompt initiation of a regimen with the appropriate empiric antimicrobial.
4. Anthrax is a highly virulent, lethal infection; human-to-human transmission, however, has not been documented.
5. Rapid recognition of botulism based on clinical presentation is essential to ensure antitoxin therapy within 24 hours of presentation.
6. Primary septicemic plague can lead to severe complications, such as multi-organ dysfunction and adult respiratory distress syndrome.
7. Smallpox vaccine stockpiles are maintained for response to a smallpox emergency.
8. Pharmacologic treatment of viral hemorrhagic fever, with the exception of infection caused by viruses from the *Filoviridae* or *Flaviviridae* family, includes oral or intravenous ribavirin.
9. Infectious disease outbreaks following natural disasters, like bioterror agent exposures, can cause panic, social unrest, and tax any country's medical and public health system.

The fall of 2001 forever changed how many people throughout the world felt about flying, airport security, and even opening their mail. Terrorism, especially bioterrorism, became a common term used by the media, military analysts, government and public health officials, and the public at large. Anxiety caused by the 2001 intentional anthrax release through the United States mail system, and the ensuing exposures and deaths, was further escalated by numerous false alarms surrounding the delivery of parcels containing unidentified white powder.[1] Recent devastating natural disasters, such as tsunamis and hurricanes, have reawakened our appreciation of the power and destruction associated with natural disasters. In April 2009, a novel influenza A virus (swine-originated H1N1) caused outbreaks of respiratory illness in Mexico and the United States, leading to a declaration of a worldwide pandemic by June.[2] Later that month, the Secretary of the U.S. Department of Health and Human Services, determined that a nationwide public health emergency existed.[3] With goals of reducing transmission and illness severity, the CDC's Division of the Strategic National Stockpile (SNS) released antiviral drugs, respiratory protection devices, and personal protective equipment to state departments of health, who in turn allocated supplies to local health jurisdictions.[4] Vaccine development and distribution, as well as execution of immunization campaigns for recommended targeted groups, was tasked to health departments. Management of stockpiles of antibiotics, antivirals, or vaccines for bioterrorism attacks or pandemic influenza is becoming a crucial public health issue. Healthcare providers need to play an active role in awareness and preparedness for biological threats released by terrorists or nature, and the decision-making process regarding postexposure prophylaxis (PEP), mass vaccination, and treatment of biologic exposures to help protect the public.

CHAPTER 16

Emergency Preparedness: Identification and Management of Chemical and Radiologic Exposures

GREENE SHEPHERD AND RICHARD B. SCHWARTZ

KEY CONCEPTS

1. In mass casualty events with chemical or radiologic exposure, the majority of victims can be managed with decontamination, observation, and supportive care. Antidotal therapies should be reserved for more critically injured victims.
2. Nerve agent poisoning is similar to organophosphate insecticide poisoning, with atropine and pralidoxime being the primary antidotes.
3. Cyanide gas exposure can be rapidly fatal but most victims that are conscious upon arrival to the hospital will not require antidote therapy.
4. Respiratory problems caused by pulmonary agents with low water solubility may take several hours to develop, thus requiring extended observation.
5. Vesicant chemical weapons are less lethal than other chemical weapons but cause significant morbidity, leaving many survivors who need extensive care.
6. Therapeutic agents are available that can block the uptake or enhance the elimination of radioactive contamination.
7. Clinicians, especially pharmacists, need to be prepared to take an active role in the design and operations of disaster plans for their workplace and community. Pharmacists may participate on established disaster response teams, which may be deployed to assist in the care of individuals outside of their local area.

Life-threatening hazardous material exposures may happen anywhere and at any time. The exposure may be due to an unintentional release or at the other extreme be the result of an intentional and catastrophic act of terrorism.[1–6] A hazardous material is defined as any substance that poses a substantial risk to the health or safety of individuals, or the environment when improperly handled, stored, transported, or disposed.[1] The specific risks are dependent on the quantity and concentration of the substance exposure and the physical, chemical, or infectious characteristics of the material. Many of these substances have the potential to be used as weapons. Small quantities of hazardous materials are used in many commercial products, such as pesticides. Larger and more concentrated quantities are found at industrial sites and in their waste byproducts. Injuries from hazardous materials are relatively common as evidenced by the tens of thousands of hazardous material incidents recorded by the U.S. Environmental Protection Agency during the last decade. The majority of these incidents occur during transport rather than at the site of manufacture or use and represent a complex and significant danger for emergency healthcare workers.[1] Violent acts of nature, such as hurricanes or earthquakes, can lead to environmental contamination due to the release of a wide variety of hazardous materials when pipelines or storage tanks rupture. At the other extreme, a hazardous material exposure may be the result of an intentional and catastrophic act of terrorism. Historically, acts of chemical or radiologic terrorism have been rare but have had very high visibility and marked psychological impact. Terrorism represents a profound threat to many countries around the world. Terrorists, whether representing foreign governments, organized religious sects, or individuals, have the capacity to endanger our communities with hazardous materials. Even a single patient contaminated with a hazardous material has the potential to overwhelm an unprepared healthcare facility.

SECTION 2
CARDIOVASCULAR DISORDERS

CHAPTER 17

Cardiovascular Testing

RICHARD A. LANGE AND L. DAVID HILLIS

KEY CONCEPTS

1. A careful patient history and physical examination are extremely important in diagnosing cardiovascular disease and should be done prior to any test.
2. Heart sounds and heart murmurs are important in identifying heart valve abnormalities and other structural cardiac defects.
3. Elevated jugular venous pressure is an important sign of heart failure and may be used to assess severity and response to therapy.
4. Electrocardiography is useful for determining rhythm disturbances (tachy- or bradyarrhythmias).
5. Exercise stress testing provides important information concerning the likelihood and severity of coronary artery disease; changes in the electrocardiogram, blood pressure, and heart rate are used to assess the response to exercise.
6. Cardiac catheterization and angiography are used to assess coronary anatomy and ventricular performance.
7. Echocardiography is used to assess valve structure and function as well as ventricular wall motion; transesophogeal echocardiography is more sensitive for detecting thrombus and vegetations than transthoracic echocardiography.
8. Radionuclides such as technetium-99m and thallium-201 are used to assess ischemia and myocardial viability in patients with suspected coronary artery disease and heart failure.
9. Pharmacologic stress testing is used when patients cannot perform physical exercise to assess the likelihood of coronary artery disease.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

In the United States, cardiovascular disease (CVD) afflicts an estimated 80 million people (i.e., approximately 1 in 3 adults) and accounts for 35% of all deaths. In 2009, the estimated direct and indirect cost of CVD—which includes hypertension, coronary heart disease, heart failure, and stroke—was $475.3 billion.[1]

Atherosclerosis, the cause of most CVD events, is typically present for decades before symptoms appear. With a thorough history, comprehensive physical examination, and appropriate testing, the individual with subclinical CVD usually can be identified, and the subject with symptomatic CVD can be assessed for the risk of an adverse event and can be managed appropriately.

THE HISTORY

The elements of a comprehensive history include the chief complaint, current symptoms, past medical history, family history, social history, and review of systems.

The chief complaint is a brief statement describing the reason the patient is seeking medical attention. The patient is asked to describe his or her current symptoms, including their duration, quality, frequency, severity, progression, precipitating and relieving factors, associated symptoms, and impact on daily activities.

The past medical history may reveal previous cardiovascular problems, conditions that predispose the patient to develop CVD (i.e., hypertension, hyperlipidemia, or diabetes mellitus) (Table 17–1), or comorbid conditions that influence the identification or management of CVD. The patient should be asked about social habits that affect the cardiovascular system, including diet, amount of regular physical activity, tobacco use, alcohol intake, and illicit drug use. At present, family history is the best available screening tool to identify patients with a genetic predisposition for CVD.

CARDIOVASCULAR HISTORY

1. Chest pain is a frequent symptom and may occur as a result of myocardial ischemia (angina pectoris) or infarction or a variety of noncardiac conditions, such as esophageal, pulmonary, or musculoskeletal disorders. The quality of chest pain, its location and duration, and the factors that provoke or relieve it are important in ascertaining its etiology.

TABLE 17-1 Risk Factors for Cardiovascular Disease

Non-Modifiable
Advancing age
Male
Family history of early onset CVD
Postmenopausal status
Modifiable
Hypertension
Diabetes mellitus
Dyslipidemia
Cigarette smoking
Obesity
Physical inactivity
Excessive alcohol
Stress
Chronic inflammation (i.e., gingivitis, arthritis, elevated C-reactive protein, etc.)
Illicit drug use (e.g., cocaine or methamphetamine)

Typically, patients with angina describe a sensation of heaviness or pressure in the retrosternal area that may radiate to the jaw, left shoulder, back, or left arm. It typically lasts only a few minutes. It is precipitated by exertion, emotional stress, eating, smoking a cigarette, or exposure to cold, and it is usually relieved with rest or a sublingual nitroglycerin, although the latter also is effective in relieving chest pain due to esophageal spasm. Angina that is increasing in severity, longer in duration, or occurring at rest is called unstable angina; it should prompt the patient to seek medical attention expeditiously.

The patient with congestive heart failure and pulmonary vascular congestion may complain of shortness of breath (dyspnea) with exertion or even at rest, orthopnea, paroxysmal nocturnal dyspnea, and nocturia. The patient with congestive heart failure and peripheral venous congestion may report abdominal swelling (from hepatic congestion or ascites), nausea, vomiting, lower extremity edema, fatigue, and dyspnea.

The New York Heart Association (NYHA) grading system is used to indicate whether a patient has angina or symptoms of congestive heart failure with vigorous (Class I), moderate (Class II), mild (Class III), or minimal/no (Class IV) exertion.

PHYSICAL EXAMINATION

The patient with suspected heart disease should undergo a comprehensive physical examination, with particular attention to the cardiovascular system. This should include an assessment of the jugular venous pulse, carotid and peripheral arterial pulses, examination of the heart and lungs (i.e., palpation, percussion, and auscultation), and inspection of the abdomen and extremities.

JUGULAR VENOUS PRESSURE

3 The jugular venous pressure (JVP) is an indirect assessment of right atrial pressure. With the patient lying supine at 30 degrees and his/her head rotated slightly to the left, the height of the fluid wave in the right internal jugular vein is determined relative to the sternal angle. The normal JVP is 1 to 2 cm above the sternal angle. The JVP typically is elevated in the patient with heart failure. The extent of elevation can be used to assess the severity of peripheral venous congestion, and its diminution can be used to assess the response to therapy.

ARTERIAL PULSES

The carotid arterial pulse is examined for its intensity and, concurrently with the apical impulse, for concordance within the cardiac cycle. Diminished carotid arterial pulsations may be the result of a reduced stroke volume, atherosclerotic narrowing of the carotid artery, or obstruction to left ventricular outflow, as may occur with aortic valve stenosis or hypertrophic obstructive cardiomyopathy. Conversely, very forceful, hyperdynamic, "bounding" carotid arterial pulsations may be palpated in the patient with an increased stroke volume and suggests the presence of chronic aortic valve regurgitation or a high cardiac output due, for example, to hyperthyroidism, an arteriovenous shunt, or marked anemia.

The pulses in the arms and legs also are examined. Diminished peripheral pulses suggest the presence of a reduced stroke volume or atherosclerotic peripheral arterial disease (PAD). Concomitant pallor, skin atrophy, hair loss, or ulcerations is consistent with PAD, which often coexists with coronary artery disease. To quantify the severity of PAD, systolic arterial pressure is measured in all four extremities. Normally, the systolic arterial pressure in the feet should be similar or even slightly higher than the pressure in the arms. Thus, the ratio of the systolic arterial pressures in the foot and arm (the so-called ankle-brachial index [ABI]) is normally >1.0. An ABI <0.9 suggests PAD.[2]

CHEST

In the patient with chest pain, a thorough lung examination should be performed to exclude a pulmonary cause. The anterior chest wall is palpated to assess for the presence of tenderness in the sternal area, which may indicate that the patient has costochondritis. Percussion of the posterior chest is done to determine if a pleural effusion is present. Auscultation of the anterior and posterior lung fields is performed to assess for the presence of findings suggestive of pneumonia, airway obstruction, pleural effusion, or pulmonary edema.

HEART SOUNDS

2 The typical "lub-dub" sound of the normal heart consists of the first heart sound (S_1), which precedes ventricular contraction and is due to closure of the mitral and tricuspid valves, and the second heart sound (S_2), which follows ventricular contraction and is due to closure of the aortic and pulmonic valves. Other heart sounds, which are normally not present (i.e., a third heart sound (S_3), fourth heart sound (S_4), or murmur), may indicate the presence of underlying heart disease (Fig. 17–1).

The S_3, a so-called ventricular gallop, is a low-pitched sound usually heard at the cardiac apex in early diastole (i.e., immediately after S_2). It is caused by the vibrations that occur when blood rapidly rushes from a "tense" atrium into a stiff, noncompliant ventricle. Thus, it is usually associated with decompensated congestive heart failure or intravascular volume overload. A so-called "physiologic" S_3 is heard commonly in healthy children and may persist into young adulthood.

The S_4 is a dull, low-pitched sound that is caused by the vibrations that occur when atrial contraction forces blood into a stiff, noncompliant ventricle. It is audible at the cardiac apex just before ventricular contraction (i.e., just before S_1); it is not present in the subject with a normal heart. An S_4 may be present in the patient with aortic stenosis, systemic arterial hypertension, hypertrophic cardiomyopathy, or coronary artery disease.

Murmurs are auditory vibrations resulting from turbulent blood flow within the heart chambers or across the valves. They are classified by their timing and duration within the cardiac cycle (systolic, diastolic, or continuous), location on the chest wall, intensity (grade 1 to 6, from softest to loudest), pitch (high or low frequency), and

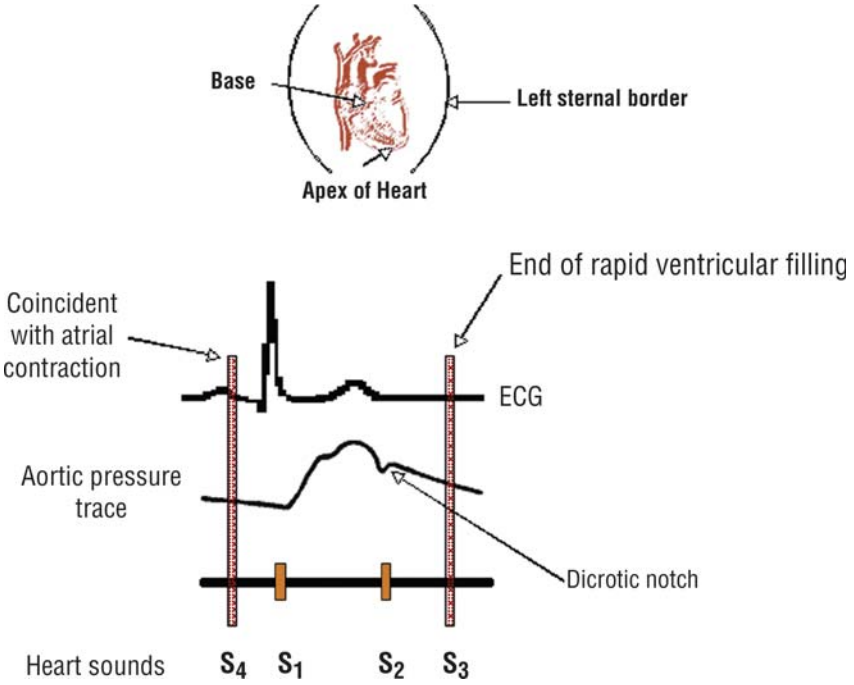

FIGURE 17-1. Correlation of the electrocardiogram (ECG) with an aortic pressure tracing and heart sounds. Normal heart sounds are S_1 (mitral and tricuspid valve closure) and S_2(aortic and pulmonic valve closure). The S_3 and S_4 "gallops" are usually abnormal. The S_3 occurs in early diastole as blood rapidly rushes into a stiff, noncompliant ventricle (e.g., with decompensated congestive heart failure). The S_4 occurs in late diastole and is caused by atrial contraction into a hypertrophied ventricle (e.g., hypertension).

radiation (Fig. 17–2 and Table 17–2). Some murmurs are said to be "innocent" or "physiologic" and result from rapid, turbulent blood flow in the absence of cardiac disease. Fever, anxiety, anemia, hyperthyroidism, and pregnancy increase the intensity of a physiologic murmur.

Systolic murmurs occur during ventricular contraction. They begin with or after S_1 and end at or before S_2, depending on the origin of the murmur. They are classified based on time of onset and termination within systole: midsystolic or holosystolic (pansystolic). Examples of midsystolic murmurs include pulmonic stenosis, aortic stenosis, and hypertrophic obstructive cardiomyopathy. Holosystolic murmurs occur when blood flows from a chamber of higher pressure to one of lower pressure throughout systole, such as occurs with mitral or tricuspid valve regurgitation or a ventricular septal defect.

Diastolic murmurs occur during ventricular filling. They begin with or after S_2, depending on the origin of the murmur. Aortic or pulmonic valve regurgitation causes a high-pitched diastolic murmur that begins with S_2, whereas stenosis of the mitral or tricuspid valves causes a low-pitched, "rumbling" diastolic murmur.

Continuous murmurs begin in systole and continue without interruption into all or part of diastole. Such murmurs are mainly a result of aortopulmonary connections (e.g., patent ductus arteriosus) or arteriovenous connections (e.g., arteriovenous fistula, coronary artery fistula, or arteriovenous malformation).

When a murmur is heard, the cardiac abnormality underlying it usually can be confirmed and assessed with echocardiography or other imaging modalities, such as cardiac angiography or magnetic resonance imaging (MRI) (see below).

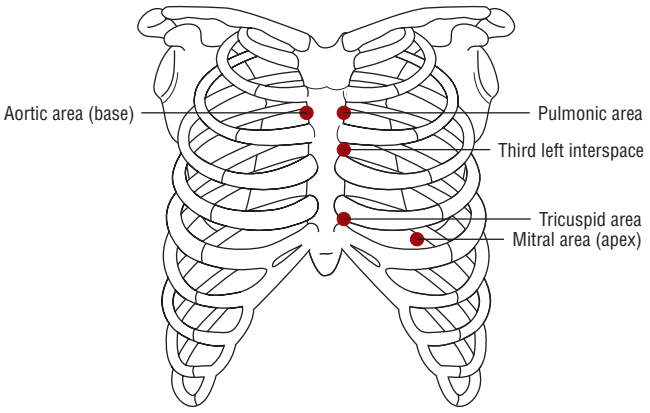

FIGURE 17-2. Schematic illustrations of topographic areas on the precordium for cardiac auscultation. Auscultatory areas do not correspond to anatomic locations of the valves but to the sites at which particular valves are heard best. *(Redrawn from Kinney MR, Packa DR, eds. Andreoli's Comprehensive Cardiac Care, 8th ed. St. Louis, MO: Mosby, 1996, with permission.)*

PRACTICE GUIDELINES FOR DIAGNOSTIC AND PROGNOSTIC TESTING IN CARDIOVASCULAR DISEASE TESTING

The American Heart Association (AHA) and American College of Cardiology (ACC) Task Force on Practice Guidelines provide the indications and utility of various diagnostic cardiac tests (Fig. 17–3). Class I indications are those for which evidence or agreement that the specific procedure is useful and effective is unequivocal. Class II indications are those for which a divergence of opinion concerning the usefulness of the test is present: class IIa are those for which evidence or opinion in favor of the test exists, whereas class IIb are those for which less evidence favoring the test is present. Class III indications are those for which evidence or agreement exists that a diagnostic test is not useful.

For a specific clinical scenario, the guidelines also indicate the level of evidence for the recommendation. Level A evidence is said to be present if the recommendation is based on the results of multiple randomized clinical trials. Level B evidence is said to exist if only a single randomized trial or multiple nonrandomized trials exist. Level C evidence is said to be present if the recommendation is made based on expert opinion only.

TABLE 17-2 Characteristic Murmurs

Murmur	Auscultatory Features	Example	Location
Mid systolic		Aortic or pulmonary stenosis	Upper sternal border
Holosystolic		Tricuspid regurgitation Mitral regurgitation	Lower sternal border Apex
Diastolic		Aortic or pulmonary regurgitation Tricuspid stenosis Mitral stenosis	Upper sternal border Lower sternal border Apex
Continuous		Arteriovenous connection Patent ductus arteriosus	Over location of connection Upper left chest

TESTING MODALITIES

BIOMARKERS

Blood tests are available for several substances that suggest the presence of myonecrosis (i.e., recent death of myocardial cells), inflammation, or hemodynamic stress (Fig. 17–4).[3–5]

Markers of Myonecrosis

When myocardial infarction (myonecrosis) occurs, proteins from the recently necrotic myocytes are released into the peripheral blood, where they can be detected using specific biochemical assays. These biomarkers of myonecrosis (a) aid in the diagnosis (or exclusion) of myocardial infarction as the cause of chest pain; (b) facilitate triage and risk stratification of patients with chest discomfort; and (c) identify patients who are appropriate candidates for specific therapeutic strategies or interventions. Cardiac troponin (cTn) is the preferred biomarker for the diagnosis of myonecrosis.[6] Other available biomarkers of necrosis include creatine kinase-MB (CK-MB) and myoglobin.

Troponin I and T are contractile proteins found only in cardiac myocytes. In the patient with myocardial infarction, cTn is detectable in the blood 2 to 4 hours after the onset of symptoms and remains detectable for 5 to 10 days (Fig. 17–5). cTn is the preferred marker for evaluating the patient suspected of having an acute myocardial infarction, since it is the most sensitive and tissue-specific biomarker available. In the patient with ischemic chest pain and electrocardiographic (e.g., ST segment) abnormalities, the presence of an elevated serum cTn concentration establishes the diagnosis of myocardial infarction, and the absence of such an elevation excludes it.

In the patient with an acute coronary syndrome, detection and quantitation of cTn in the blood provide prognostic information and guide management. Acute coronary syndrome patients with an elevated serum cTn concentration have a roughly four-fold higher risk of death and recurrent MI in the coming months when compared to those with normal cTn concentrations.[7] They benefit (i.e., have a reduced incidence of death, recurrent myocardial infarction, and recurrent ischemia) from more intensive antiplatelet and antithrombotic therapy as well as prompt coronary angiography and revascularization, whereas those with a normal serum cTn do not benefit from such intensive therapy.[8] Thus, serum cTn concentrations are used for diagnostic, prognostic, and therapeutic purposes in the patient with suspected or proven coronary artery disease.

On occasion, the serum cTn concentration may be elevated in a patient without coronary artery disease in whom myonecrosis

Size of treatment effect

Estimate of certainty (precision) of treatment effect		Class I	Class IIa	Class IIb	Class III
		Benefit >>> Risk Procedure/Treatment SHOULD be performed/ administered	Benefit >>> Risk Additional studies with focused objectives needed **IT IS REASONABLE to perform procedure/ administer treatment**	Benefit ≥ Risk Additional studies with broad objectives needed; Additional registry data would be helpful **IT IS NOT UNREASONABLE to perform procedure/ administer treatment**	Risk ≥ Benefit No additional studies needed **Procedure/Treatment should NOT be performed/ administered SINCE IT IS NOT HELPFUL AND MAY BE HARMFUL**
	Level A Multiple (3–5) population risk strata evaluated General consistency of direction and magnitude of effect	• Recommendation that procedure or treatment is useful/effective • Sufficient evidence from multiple randomized trials or meta-analyses	• Recommendation in favor of treatment or procedure being useful/effective • Some conflicting evidence from multiple randomized trials or meta-analyses	• Recommendation's usefulness/efficacy less well established • Greater conflicting evidence from multiple randomized trials or meta-analyses	• Recommendation that procedure or treatment not useful/effective and may be harmful • Sufficient evidence from multiple randomized trials or meta-analyses
	Level B Limited (2–3) population risk strata evaluated	• Recommendation that procedure or treatment is useful/effective • Limited evidence from single randomized trial or non-randomized studies	• Recommendation in favor of treatment or procedure being useful/effective • Some conflicting evidence from single randomized trial or non-randomized studies	• Recommendation's usefulness/efficacy less well established • Greater conflicting evidence from single randomized trial or non-randomized studies	• Recommendation that procedure or treatment not useful/effective and may be harmful • Limited evidence from single randomized trial or non-randomized studies
	Level C Very limited (1–2) population risk strata evaluated	• Recommendation that procedure or treatment is useful/effective • Only expert opinion, case studies, or standard-of-care	• Recommendation in favor of treatment or procedure being useful/effective • Only diverging expert opinion, case studies, or standard-of-care	• Recommendation's usefulness/efficacy less well established • Only diverging expert opinion, case studies, or standard-of-care	• Recommendation that procedure or treatment not useful/effective and may be harmful • Only expert opinion, case studies, or standard-of-care

FIGURE 17-3. Classification of recommendations and level of evidence.

occurs because myocardial oxygen demands markedly exceed oxygen supply (i.e., severe systemic arterial hypertension) or nonischemic cardiac injury occurs (i.e., myocardial contusion caused by blunt trauma to the chest) (Table 17–3). In the patient with an elevated serum cTn concentration, the responsible physician must decide if the observed abnormal serum cTn concentration is the result of coronary artery disease or another condition.

When serum cTn measurements are not available, the best alternative is the MB isoenzyme of creatine kinase (CK-MB), which is a cytosolic carrier protein for high-energy phosphates that is released into the blood when myonecrosis occurs. Although it was initially thought to be cardiac specific, CK-MB is now known to be present in small amounts in skeletal muscle; as a result, it may be detectable in the blood of patients with massive muscle injury, as occurs with rhabdomyolysis or myositis.

In the patient with an acute myocardial infarction, CK-MB can be detected in the blood 2 to 4 hours after symptom onset; its serum concentration peaks within 24 hours, and it remains detectable in the blood for 48 to 72 hours. To document the characteristic rise and fall of CK-MB concentrations, blood samples should be obtained every 4 to 8 hours. Although CK-MB is not as sensitive or cardiac-specific a biomarker as cTn, its blood concentration declines more rapidly than cTn, which makes

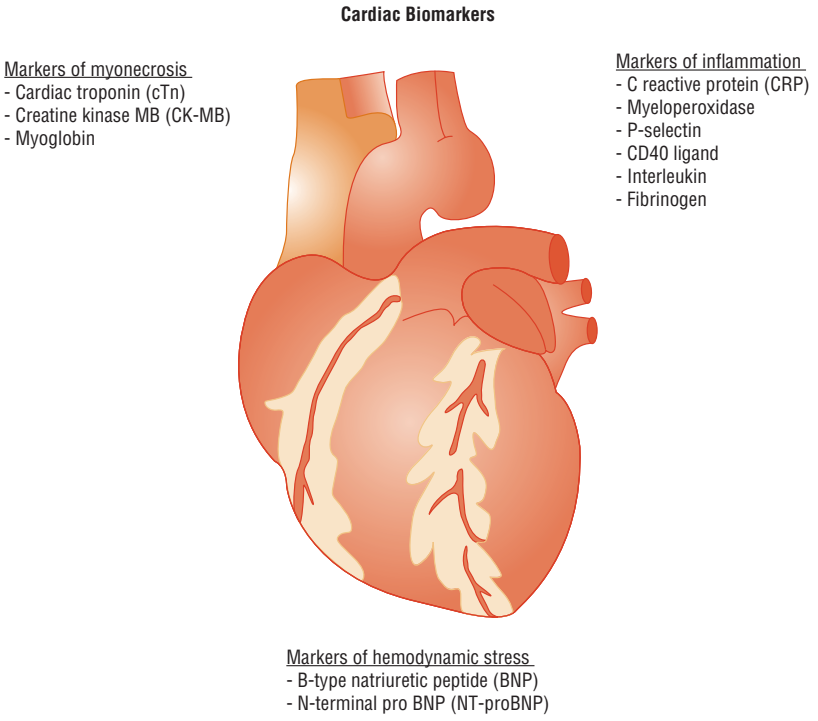

FIGURE 17-4. Cardiac biomarkers classified according to the different pathologic processes they indicate.

it the preferred biomarker for evaluating suspected recurrent infarction in the patient who experiences recurrent chest pain within several days of myocardial infarction. With recurrent infarction, the typical rise and fall of the serum CK-MB concentration is interrupted by a second elevation. Since serum cTn concentrations decline slowly following myocardial infarction, they are not as sensitive as CK-MB for diagnosing recurrent infarction.

The serum myoglobin concentration is elevated in the patient with myonecrosis, but it has a low specificity for myocardial infarction because of its high concentration in skeletal muscle. Because of its small molecular size and consequent rapid release (within 1 hour) following the onset of myonecrosis, it is valuable as a very early marker of myocardial infarction. When it is combined with a more specific marker of myonecrosis, such as cTn or CK-MB, myoglobin is useful for the early exclusion of myocardial infarction.

Markers of Inflammation

Inflammatory processes participate in the development of atherosclerosis and contribute to the destabilization of atherosclerotic plaques, which may ultimately lead to an acute coronary syndrome. Several mediators of the inflammatory response, including acute phase proteins, cytokines, and cellular adhesion molecules, have been evaluated as potential indicators of underlying atherosclerosis and as predictors of acute cardiovascular events.

C-reactive protein (CRP) is an acute-phase reactant protein produced by the liver.[9] Although a receptor for CRP is present on endotheial cells, controversy exists regarding whether CRP is simply a marker for systemic inflammation or participates actively in atheroma formation.[10,11] In the absence of acute illness or myocardial infarction, serum concentrations of CRP are relatively stable, although their concentrations are influenced by gender and ethnicity.

Epidemiologic studies have shown that the relative risk of future vascular events increases as the serum hs-CRP concentration increases.[9] Values >3 mg/L are associated with an increased risk for developing CVD; conversely, values <1 mg/L are associated with a low risk. Those between 1 and 3 mg/L are considered to be

TABLE 17-3 Conditions Associated With an Increased Serum Troponin Concentration

Myocardial infarction	Pulmonary embolism
Acute coronary syndrome	Strenuous exercise
Coronary intervention	Chemotherapy
Pericarditis	Severe asthma
Congestive heart failure	Respiratory distress
Cardiac defibrillation	Infiltrative disorders
Cardiac ablation	Acute limb ischemia
Cardiac contusion	Inflammatory disease
Tachycardia	Influenza
Aortic dissection	Hemodialysis
Stroke	Sepsis
Renal failure	Shock
Hyper- or hypotension	Rhabdomyolysis

at intermediate risk. To measure serum CRP concentrations accurately, a high-sensitive CRP (hs-CRP) assay is required. In an individual with an elevated serum CRP concentration, the measurement should be repeated several weeks later to exclude the possibility that an acute illness was responsible for the elevation. Measurements should not be taken when subjects are acutely ill (for example, with any acute febrile illness) or have a known autoimmune or rheumatologic disorder. Serum CRP concentrations above 10 mg/L are likely caused by an acute or chronic systemic illness.[12]

Although the relative risk of future vascular events increases as the serum concentration of hs-CRP increases, controversy continues as to whether hs-CRP concentrations provide sufficient incremental information above traditional risk factors to warrant routine testing in subjects without known CVD in an attempt to prevent an adverse event (so-called primary prevention).[9,13] Recent guidelines have suggested that CRP be used in patients who are considered (on the basis of traditional risk factors) to be at intermediate risk for coronary artery disease in an attempt to guide the intensity with which their risk factors are modified.[9] Only limited data have suggested that interventions that lower CRP concentrations (i.e., aspirin and statins) are beneficial.[14–16]

Multiple studies[17,18] of patients with acute coronary syndromes have demonstrated the capacity of hs-CRP concentrations—measured at the time of hospitalization or hospital discharge—to help to predict cardiovascular outcomes during the hospitalization or during long-term follow-up. This prognostic information appears to be independent of and complementary to data obtained from the history and electrocardiogram. Moreover, hs-CRP concentrations appear to provide additional prognostic information in patients with a normal cTn concentration,[19] and they may be useful for monitoring the response to statin therapy, in that those with low hs-CRP concentrations after statin therapy have better clinical outcomes than those in whom these concentrations are high.[14,16] Based on these data, the measurement of serum hs-CRP concentrations in patients with acute coronary syndromes is recommended as reasonable (class IIa) for risk stratification when additional prognostic information is desired.[5] In contrast, its routine use is not recommended in the absence of compelling data identifying its role in guiding specific therapy.

Other novel markers of inflammation that have been shown to provide prognostic information in patients with an acute coronary syndrome are myeloperoxidase, CD40 ligand, and P-selectin (a marker of platelet activation and a potential participant in plaque destabilization), interleukin 6, and fibrinogen.[3,5]

Markers of Hemodynamic Stress

B-type natriuretic peptide (BNP) and its precursor, N-terminal pro-brain natriuretic protein (NT-proBNP), are released from ventricular myocytes in response to increases in wall stress. As a result, their serum concentrations typically are increased in patients with congestive heart failure. They may also be elevated in patients with an acute coronary syndrome as a result of left ventricular systolic dysfunction, impairment of ventricular relaxation, and myocardial stunning.[5]

Since serum BNP and NT-proBNP concentrations manifest substantial biologic variability, their serum concentrations in an individual subject must increase or decrease at least 2-fold to provide assurance that a "real" change has occurred. In addition, when considering the normal range for an individual, one must be aware that considerable variation in serum concentrations exists according to age, gender, weight, and renal function. Women and older patients have a higher normal range, whereas obese patients have lower values than the nonobese. Patients with renal failure often have substantially higher values.

Elevated BNP and NT-proBNP concentrations support a suspected diagnosis of heart failure or lead to a suspicion of heart failure when a diagnosis is unclear. Conversely, a normal value (BNP <100 pg/mL or NT-proBNP <300 pg/mL) in an untreated patient strongly suggests that heart failure is not present.[20,21] In a study of 1,568 patients seeking medical attention because of acute dyspnea, plasma BNP was significantly higher in those with clinically diagnosed heart failure than in those without (mean value, 675 compared with 110 pg/mL, respectively), with intermediate values in those with known heart failure but with a noncardiac cause of dyspnea (mean, 346 pg/mL).[22]

Plasma BNP concentrations provide prognostic information in patients with acute decompensated heart failure: in-hospital mortality is 3-fold higher in those in the highest BNP quartile when compared to the lowest quartile.[23] Similarly, in patients with compensated CHF, plasma BNP concentrations provide valuable prognostic information, in that each 100 pg/mL increase in plasma BNP in these subjects is associated with a 35% increase in the relative risk of death.[24] Although the measurement of BNP can be used for prognostic purposes in patients with CHF, its role in assessing treatment efficacy and modifying drug therapy is not clearly established.

Elevated plasma concentrations of BNP and NT-pro BNP have been observed in subjects with heart failure with depressed left ventricular systolic function, heart failure with preserved left ventricular systolic function, elevated left ventricular filling pressures, left ventricular hypertrophy, atrial fibrillation, and myocardial ischemia. They may be elevated in certain noncardiac conditions, including pulmonary embolism, chronic obstructive pulmonary disease, hypoxemia, sepsis, cirrhosis, and renal failure. As a result, values of BNP or NT-pro BNP should not be used in isolation either to confirm or to refute a diagnosis of heart failure.

Elevated serum concentrations of BNP and NT-proBNP may be detected in patients with acute coronary syndrome. Data from at least 10 studies have indicated that BNP and NT-proBNP are among the most robust predictors of death and heart failure in patients hospitalized with acute coronary syndrome.[5,25–27] Nonetheless, data regarding the potential for these substances to guide specific therapeutic decisions, such as whether to perform coronary angiography and revascularization, have been mixed. At present, therefore, the use of BNP and NT-proBNP in patients with acute coronary syndrome is limited to risk stratification, for which they can be used to help in the assessment of prognosis.

CHEST RADIOGRAPHY

The chest radiograph provides supplemental information to the physical examination. Although it does not provide detailed information about internal cardiac structures, it can provide information about the position and size of the heart and its chambers as well as adjacent structures. The standard chest radiographs for evaluation of the lungs and heart are standing posteroanterior and lateral views taken with maximal inspiration; portable chest radiographs usually are less helpful. When possible, previous radiographs should be obtained for comparison.

The posteroanterior chest radiograph outlines the superior vena cava, right atrium, aortic knob, main pulmonary artery, left atrial appendage (especially if enlarged), and left ventricle. In the lateral view, the chest radiograph allows one to assess the right ventricle, inferior vena cava, and left ventricle. These structures are visualized as shadows of differing density rather than as discrete entities.

Cardiac enlargement is determined by the cardiothoracic ratio (CTR), which is the maximal transverse diameter of the heart divided by the maximal transverse diameter of the thorax on the posteroanterior view. The CTR normally is ≤0.45, but it may be higher (i.e., ≤0.55) in subjects with a large stroke volume (e.g., highly conditioned athletes). Certain cardiac conditions, such as heart failure and hypertension, may cause cardiac enlargement,

with a resultant high CTR. Individual chamber enlargement can be seen on the chest radiograph. Right ventricular enlargement is best seen on the lateral film, on which the heart appears to occupy the retrosternal space. Left atrial enlargement is suspected if there is elevation of the left bronchus or an enlarged atrial appendage. Left ventricular enlargement is the most common feature identified on chest radiography and is seen as a lateral and downward displacement of the cardiac apex. A large pericardial effusion may appear as a large heart on a chest radiograph, but, in contrast to heart failure, pulmonary vascular congestion is not present (see below).

The pulmonary vessels are examined for size and filling. With diminished pulmonary blood flow, as would be present in the patient with tetralogy of Fallot or pulmonic valvular stenosis, the peripheral pulmonary vessels are small in caliber and under-filled. Increased pulmonary blood flow, as occurs with a high cardiac output or left-to-right intracardiac shunting, may lead to enlargement and tortuosity of the central and peripheral pulmonary vessels. Pulmonary arterial hypertension (increased pulmonary resistance) is identified by enlargement of the central pulmonary arteries and diminished peripheral perfusion. Elevated pulmonary venous pressure—usually as a result of an elevated left atrial pressure—is characterized by dilation of vessels in the upper lung zones (e.g., cephalization of flow), owing to recruitment of upper lung vessels when blood is diverted from the constricted vessels in the lower lung zones.

Congestive heart failure causes Kerley B lines (edema of interlobular septa), which appear as thin, horizontal reticular lines in the costophrenic angles. As pulmonary venous pressure increases, alveolar edema becomes evident, and pleural effusions may appear as blunting of the costophrenic angles.

ELECTROCARDIOGRAPHY

4 The electrocardiogram (ECG) is a graphic recording of the electrical potentials generated by the heart. The signals are detected by using electrodes attached to the extremities and chest wall (Figs. 17–6 and 17–7), which are then amplified and recorded (Fig. 17–8). The ECG leads display the instantaneous differences in potential between electrodes. As electrical activity approaches the positive electrode of the lead, it registers a positive (upright) deflection on the ECG, whereas electrical activity in the opposite direction of the positive electrode of the lead registers a negative (downward) deflection.

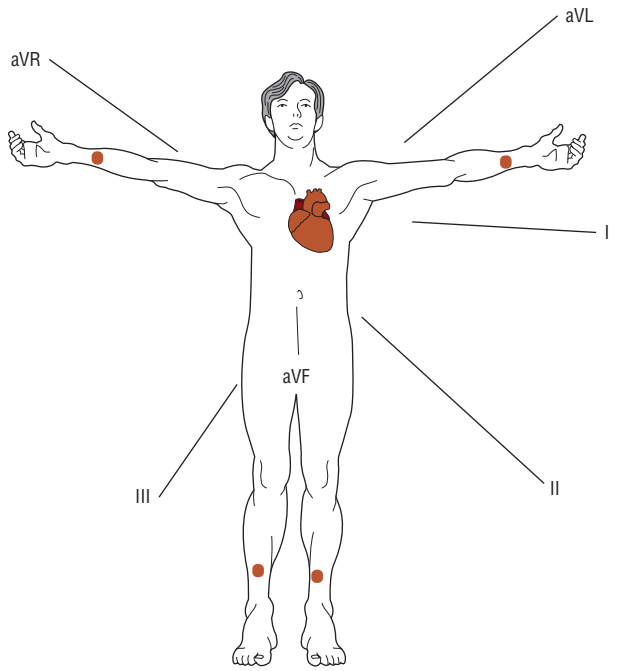

FIGURE 17-6. With electrodes (depicted as dots) attached to each arm and leg, electrical activity on the torso (i.e., frontal plane) is recorded from six different directions. These are known as the limb leads; leads I, II, III, aVF, aVL, and aVR.

The ECG can be used to detect arrhythmias, conduction disturbances, myocardial ischemia or infarction, metabolic disturbances that may result in lethal arrhythmias (e.g., hyperkalemia), and increased susceptibility to sudden cardiac death (e.g., prolonged QT interval). It is simple to perform, noninvasive, and inexpensive.

Depolarization of the heart initiates cardiac contraction. The electrical current that depolarizes the heart originates in special cardiac pacemaker cells located in the sinoatrial (SA) node, or sinus node, which is located in the upper right atrium near the insertion of the superior vena cava (Fig. 17–9). The depolarization wave is transmitted through the atria, which initiates atrial contraction. Subsequently, the impulse is transmitted through specialized conduction tissues in (a) the atrioventricular (AV) node, which is located in the inferior right atrium near the tricuspid valve; (b) the bundle of His, which is located in the interventricular septum; and (c) the right and left bundles, which rapidly conduct the electrical impulse to the right and left ventricular myocardium via (d) the Purkinje fibers. The depolarization wavefront then spreads through the ventricular muscle, from endocardium to epicardium, triggering ventricular contraction.

The ECG waveforms (Fig. 17–10), which are recorded during electrical depolarization of the heart, are labeled alphabetically and are read from left to right, beginning with the P wave, which represents depolarization of the atria. The normal duration of the P wave is up to 0.12 second. The *PR segment,* created by passage of the impulse through the AV node and the bundle of His and its branches, has a duration of 0.12 to 0.20 second. The *QRS complex* represents electrical depolarization of the ventricles. Initially, a negative deflection (the Q wave) appears, followed by a positive deflection, the R wave, and finally a negative deflection, the S wave. The normal duration of the QRS complex is <0.12 second. Since the left ventricle is much thicker than the right ventricle, most of the electrical wavefront is directed toward the former. Accordingly, the precordial leads positioned over the left ventricle (leads V_5 and V_6) demonstrate a positive (upright) QRS complex, whereas those positioned over the right ventricle (V_1 and V_2) record a negative (downward) QRS complex.

Following the QRS complex is a plateau phase called the *ST segment,* which extends from the end of the QRS complex (called the *J point*) to the beginning of the T wave. When ischemia occurs, one may observe depression of the ST segment (Fig. 17–11A). When infarction from total obstruction of a coronary artery occurs, ST segment elevation may be observed (Fig. 17–11B). Repolarization of the ventricle leads to the T wave. The T wave usually goes in the same direction as the QRS complex.

The *QT interval*—measured from the beginning of the QRS complex to the end of the T wave—includes the time required for ventricular depolarization and repolarization, and it varies inversely with heart rate. A rate-related ("corrected") QT interval (QTc) can be calculated as QT$\sqrt{}$R-R interval; it should be <0.44 second. A prolonged QTc interval is caused by abnormalities in depolarization or repolarization that are associated with sudden cardiac death. QTc prolongation may be due to genetic defects in action potential ion channels (e.g., congenital long QT syndrome), drugs (Table 17–4), or electrolyte disturbances (i.e., hypokalemia, hypocalcemia, hypomagnesemia). Regardless of the cause, QT prolongation increases susceptibility to a potentially lethal arrhythmia, torsades de pointes (a type of ventricular tachycardia).

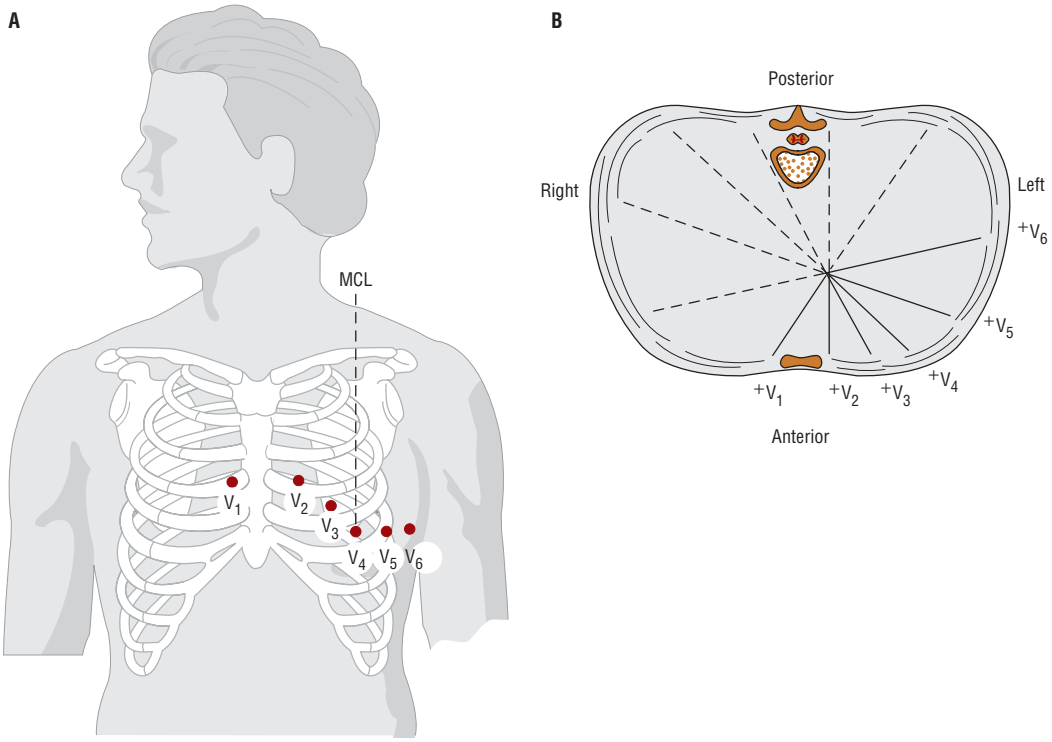

FIGURE 17-7. **A.** Electrode positions of the precordial leads. (MCL, midclavicular line; V1, fourth intercostal space at the right sternal border; V_2, fourth intercostal space at the left sternal border; V_3, halfway between V_2 and V_4; V_4, fifth intercostal space at the midclavicular line; V_5, anterior axillary line directly lateral to V_4; V_6, anterior axillary space directly lateral to V_5.). **B.** The precordial reference figure. Leads V_1 and V_2 are called right-sided precordial leads; leads V_3 and V_4, midprecordial leads; and leads V_5 and V_6, left-sided precordial leads. *(Redrawn from Kinney MR, Packa DR, eds. Andreoli's Comprehensive Cardiac Care, 8th ed. St. Louis: Mosby, 1996, with permission.)*

The 12 conventional ECG leads record the electrical potential difference between electrodes placed on the surface of the body (Fig. 17–9). The 6 frontal plane and the 6 horizontal plane leads provide a three-dimensional representation of cardiac electrical activity. Each lead provides the opportunity to view atrial and ventricular depolarization from a different angle, much the same way that multiple video cameras positioned in different locations can view an event from different perspectives.

The 6 frontal leads can be subdivided into those that view electrical potentials directed inferiorly (leads II, III, aVF), laterally

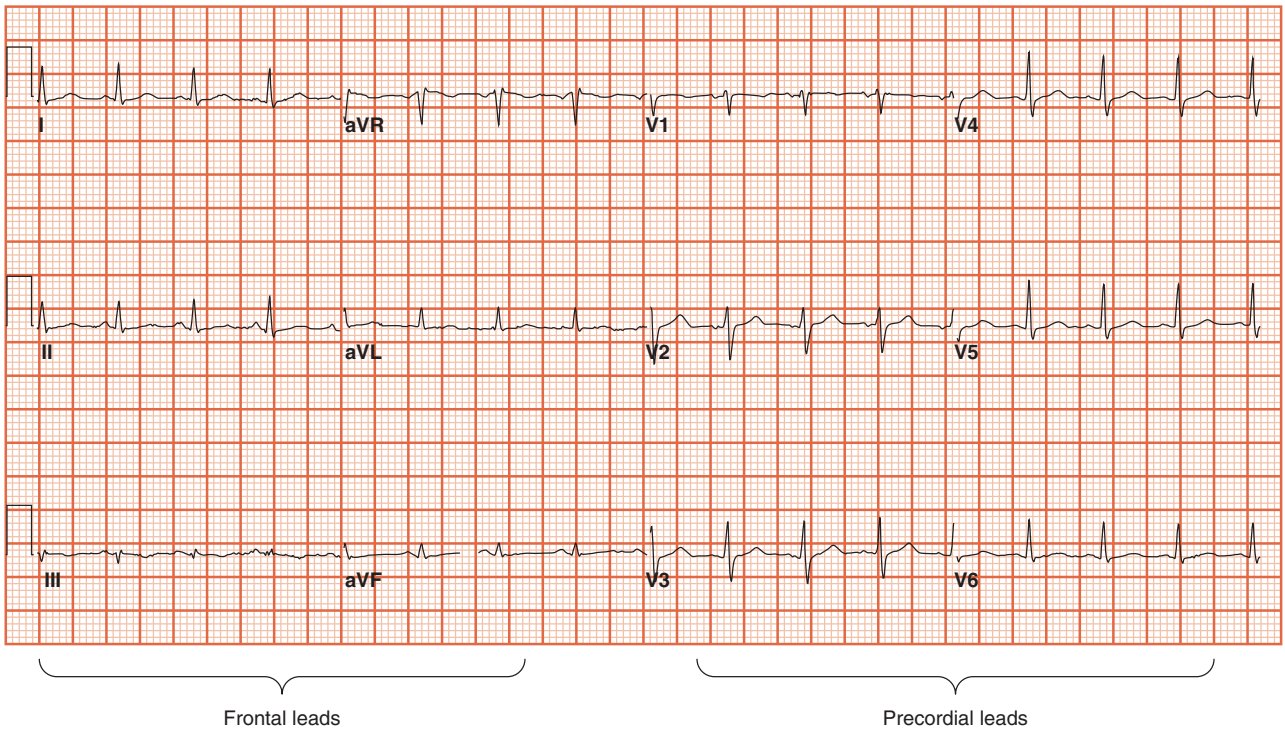

FIGURE 17-8. Standard 12-lead electrocardiogram, with 6 frontal and 6 precordial leads.

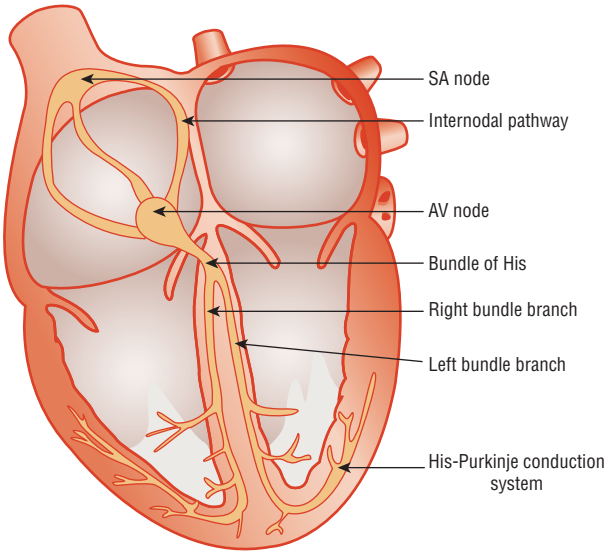

FIGURE 17-9. Schematic representation of the cardiac conduction system. (AV, atrioventricular; SA, sinoatrial.) *(From Vijayaraman P, Ellenbogen KA. Bradyarrhythmias and Pacemakers. In: Fuster V, O'Rourke RA, Walsh RA, Poole-Wilson P: Hurst's the Heart, 12th ed. New York: McGraw-Hill, 2004:1021.)*

(leads I, aVL), or rightward (aVR). Likewise, the 6 precordial leads can be subdivided into those that view electrical potentials directed toward the septal (leads V_1, V_2), apical (leads V_3, V_4), or lateral (leads V_5, V_6) regions of the heart. Thus, when ischemia or infarction-related ECG changes occur, the region of the heart affected can be localized by determining which leads manifest abnormalities.

The mean orientation of the QRS vector with reference to the 6 frontal plane leads is known as the QRS axis. It describes the "major" direction of QRS depolarization, which is typically toward the apex of the heart (i.e., toward the left side of the chest and downward). An abnormality in the direction of QRS depolarization (so-called axis deviation) may occur with hypertrophy or enlargement of one or more cardiac chambers or with remote myocardial infarction, since electrical depolarization is not transmitted through dead tissue. Hypertrophy or enlargement of the atria or ventricles may also affect the size of the P wave or QRS complex. Although specific ECG criteria have been developed for diagnosing hypertrophy, the ECG is neither sensitive nor specific for establishing the presence of atrial dilatation or ventricular hypertrophy. Other noninvasive modalities (i.e., echocardiography or MRI) are superior to the ECG for evaluating these conditions.

The origin of the electrical impulses (the so-called cardiac rhythm) and integrity of the conduction system can be assessed with a 12-lead ECG. If the SA node is diseased and unable to initiate cardiac depolarization, specialized cardiac pacemaker cells in the AV node or ventricle may initiate cardiac depolarization instead, albeit at a slower rate than the SA node. Alternatively, the SA node may initiate the electrical impulse, but its transmission through the specialized conduction system may be slowed or interrupted in the AV node or bundle of His, resulting in first degree or advanced (i.e., second or third degree) AV block, respectively. Finally, disease in the left or right bundle may slow conduction of the electrical impulse, resulting in a left or right bundle-branch block, respectively.

The ECG provides an assessment of the heart rate, which is normally 60 to 100 beats per minute (bpm) at rest. Tachycardia is present when the heart rate exceeds 100 bpm, and bradycardia is present when it is <60 bpm. Tachycardia may originate in the SA node (sinus tachycardia), atrium (atrial flutter or fibrillation, ectopic atrial tachycardia, or multifocal atrial tachycardia), or AV node (junctional tachycardia or AV nodal reentry tachycardia). Collectively, these are termed supraventricular tachycardias. Alternatively, a tachycardia may have its origin in the right or left ventricle (ventricular tachycardia, ventricular fibrillation, and right ventricular outflow tract tachycardia).

Many drugs can affect the specialized cardiac pacemaker cells, causing tachycardia or bradycardia, or the conduction system, which may lead to AV block or sudden cardiac death. A resting ECG should be performed before and after the administration of such drugs, with examination of the rhythm, heart rate, and various intervals (i.e., PR, QRS, and QT) to determine if substantial changes have occurred.

In the patient with chest pain, the resting ECG is examined for ST segment abnormalities that may indicate myocardial ischemia or infarction (i.e., ST segment depression or elevation). In addition, the resting ECG may indicate if the patient has had a remote myocardial infarction.

The ECG is used often in conjunction with other diagnostic tests to provide additional data, monitor the patient, or determine if symptoms correlate with what is observed on the ECG. For example, the patient suspected of having coronary artery disease may undergo stress testing with ECG monitoring to assess the presence of provocable ischemia.

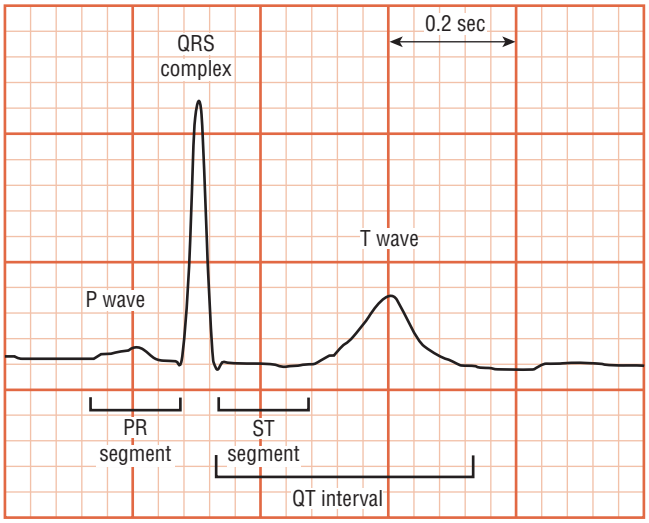

FIGURE 17-10. ECG waveforms are labeled alphabetically and are read from left to right. The *P wave* represents depolarization of the atria. The *PR segment* is created by passage of the impulse through the atrioventricular node and the bundle of His and its branches. The *QRS complex* represents electrical depolarization of the ventricles. The *T wave* results from ventricular depolarization. A plateau phase called the *ST segment* extends from the end of the QRS complex to the beginning of the T wave. The ST segment elevates with infarction and depresses with ischemia. The *QT interval*—measured from the beginning of the QRS complex to the end of the T wave—includes the time required for ventricular depolarization and repolarization.

Signal-Averaged ECG

Survivors of myocardial infarction may be at risk for life-threatening arrhythmias. In these individuals, myocardial scar tissue creates zones of slow conduction that appear as low amplitude, high frequency signals that are continuous with the QRS complex. These small electrical currents (so-called late potentials) are not detectable on a routine, traditional ECG. By using computer programs that amplify and enhance the electrical signal, signal-averaged electrocardiography (SAECG) provides a high-resolution ECG that measures ventricular

FIGURE 17-11. *A.* Electrocardiogram recorded during an episode of chest pain at rest in a patient with unstable angina. ST-segment depression >1 mm is present in leads V_4 to V_6. *B.* EKG from a patient with acute myocardial infarction. Note the ST segment elevation in the inferior (leads III and aVF) and precordial (leads V_1–V_6) leads, indicating that the inferior and anterior regions of the heart are affected. *(From Vijayaraman P, Ellenbogen KA. Bradyarrhythmias and Pacemakers. In: Fuster V, O'Rourke RA, Walsh RA, Poole-Wilson P: Hurst's the Heart, 12th ed. New York: McGraw-Hill, 2004:1046.)*

late potentials, thereby identifying patients at risk of sustained ventricular tachycardia after myocardial infarction.[28]

Patients with ischemic heart disease and unexplained syncope who are at risk for sustained ventricular tachycardia may be candidates for a SAECG. A SAECG may be useful in the patient with nonischemic cardiomyopathy and sustained ventricular tachycardia, detection of acute rejection following heart transplant, and assessment of the proarrhythmic potential of antiarrhythmic drugs.

AMBULATORY ELECTROCARDIOGRAPHIC MONITORING

Ambulatory electrocardiography (AECG), so-called Holter monitoring, can be used to detect, document, and characterize the cardiac rhythm or ECG abnormalities during ordinary daily activities. Current continuous AECG equipment is capable of providing an analysis of cardiac electrical activity, including arrhythmias, ST segment abnormalities, and heart rate variability. An AECG can be obtained with continuous recorders (Holter monitors) or intermittent recorders.

During continuous Holter monitoring, the patient wears a portable ECG recorder (weighing 8 to 16 oz) that is attached to 2 to 4 leads placed on the chest wall. During monitoring, the patient maintains a diary, in which he/she records the occurrence, duration, and severity of symptoms (e.g., lightheadedness, chest pain, palpitations, etc). The device is typically worn for 24 to 48 hours, after which the continuous ECG recording is scanned by computer to detect arrhythmias or ST segment abnormalities.

Intermittent recorders (also known as event monitors or loop recorders) are worn for longer periods of time (weeks to months). Although they continuously monitor the ECG, only brief (minutes) segments of it are recorded when the patient activates the device (i.e., when symptoms occur) or a preprogrammed abnormal ECG event occurs. Some intermittent event recorders incorporate a memory loop that permits capture of a rhythm recording during fleeting symptoms, tachycardia onset, and, in some cases, syncope that occurs infrequently. When the patient activates a looping

TABLE 17-4 Drugs With Known Risk of QT interval Prolongation and Potentially Lethal Arrhythmia (Torsades de Pointes)

Generic	Brand	Generic	Brand
Amiodarone	Cordarone	Ibutilide	Corvert
Amiodarone	Pacerone	Levomethadyl	Orlaam
Arsenic trioxide	Trisenox	Mesoridazine	Serentil
Astemizole	Hismanal	Methadone	Dolophine
Bepridil	Vascor	Methadone	Methadose
Chloroquine	Aralen	Pentamidine	Pentam
Chlorpromazine	Thorazine	Pentamidine	NebuPent
Cisapride	Propulsid	Pimozide	Orap
Clarithromycin	Biaxin	Probucol	Lorelco
Disopyramide	Norpace	Procainamide	Pronestyl
Dofetilide	Tikosyn	Procainamide	Procan
Domperidone	Motilium	Quinidine	Cardioquin
Droperidol	Inapsine	Quinidine	Quinaglute
Erythromycin	Erythrocin	Sotalol	Betapace
Erythromycin	E.E.S.	Sparfloxacin	Zagam
Halofantrine	Halfan	Terfenadine	Seldane
Haloperidol	Haldol	Thioridazine	Mellaril

monitor, it records several minutes of the preceding rhythm as well as the subsequent rhythm.

When monitoring is performed to evaluate the cause of intermittent symptoms, the frequency of symptoms dictates the type of recording. Continuous recordings are indicated for the assessment of frequent (at least once a day) symptoms that may be related to disturbances of heart rhythm, for the assessment of syncope or near syncope, and for patients with recurrent unexplained palpitations. In contrast, for patients whose symptoms are infrequent, intermittent event recorders may be more cost-effective in attempting to determine the cause of symptoms. For patients receiving antiarrhythmic drug therapy, continuous monitoring is indicated to assess drug response and to exclude proarrhythmia.

EXERCISE STRESS TESTING

5 Exercise stress testing, a well-established, relatively low-cost procedure, has been in widespread use for decades. It may be performed (a) to evaluate an individual's exercise capacity; (b) to assess the presence of myocardial ischemia in the patient with symptoms suggestive of coronary artery disease; (c) to obtain prognostic information in the patient with known coronary artery disease or recent myocardial infarction; (d) to evaluate the severity of valvular abnormalities; or (e) to assess the presence of arrhythmias or conduction abnormalities in the patient with exercise-induced cardiac symptoms (i.e., palpitations, lightheadedness, or syncope).

The patient who is to undergo an exercise stress test should fast for several hours beforehand and dress appropriately for exercise. Before exercise begins, a limited cardiac examination is performed (i.e., auscultation of the lungs and heart); blood pressure and heart rate are measured and the values recorded; and a standard 12-lead ECG is recorded. Exercise is then initiated, and the ECG, heart rate, and blood pressure are monitored carefully and recorded as the intensity of exercise increases incrementally. The patient is monitored for the development of symptoms (i.e., chest pain, dyspnea, lightheadedness, etc.), transient rhythm disturbances, ST segment abnormalities, and other electrocardiographic manifestations of myocardial ischemia. Exercise is terminated with the onset of limiting symptoms, diagnostic electrocardiographic (e.g., ST segment) changes, arrhythmias, or a decrease in blood pressure >10 mm Hg. Otherwise, exercise is continued until the patient achieves 85% of his or her maximal predicted heart rate or is unable to exercise further.

Both treadmill and cycle ergometer devices are available for exercise testing. Although cycle ergometers are less expensive, smaller, and quieter than treadmills, quadricep muscle fatigue is a major limitation in patients who are not experienced cyclists, and subjects usually stop cycling before reaching their maximal oxygen uptake. As a result, treadmills are much more commonly used for exercise stress testing, particularly in the United States.

With treadmill testing, the incline and/or speed of the treadmill is increased incrementally every 2 to 3 minutes. Several treadmill exercise protocols have been developed to accommodate the variations in fitness, age, and mobility of individuals. Accordingly, if the exercise capacity is reported in minutes, the details of the protocol should be specified. Alternatively, the translation of exercise duration or workload into METs (oxygen uptake expressed in multiples of basal oxygen uptake, 3.5 mLO_2/kg/min) has the advantage of providing a common measure of performance regardless of the type of exercise test or protocol used. Most domestic chores and activities require <5 METs, whereas participation in strenuous sports, such as swimming, singles tennis, football, basketball, or skiing, requires >10 METs.

Interpretation of the results of exercise testing should include exercise capacity as well as the clinical, hemodynamic, and electrocardiographic responses. The occurrence of chest pain consistent with angina is important, particularly if it results in termination of the test. Abnormalities in exercise capacity, the response of systolic blood pressure to exercise, and the response of heart rate to exercise and recovery may provide valuable information. The most important electrocardiographic findings are ST segment depression and elevation. A positive exercise test is said to have occurred if the ECG shows at least 1 mm of horizontal or downsloping ST segment depression or elevation for at least 60 to 80 milliseconds after the end of the QRS complex.

ST segment changes suggestive of myocardial ischemia that occur at a low level of exercise (<6 minutes of exercise or <5 METS) are associated with more severe coronary artery disease and a worse prognosis than those that occur at a higher workload. An estimate of myocardial oxygen demands can be obtained by calculating the so-called "rate-pressure product" (double product) (i.e., heart rate × systolic arterial pressure).

Most treadmill exercise testing is performed in adults with symptoms of known or suspected ischemic heart disease. In patients for whom the diagnosis of coronary artery disease is certain, stress testing is often used for risk stratification or prognostic assessment to determine the need for possible coronary angiography or revascularization. Patients who are candidates for exercise testing may (a) have stable chest pain; (b) be stabilized by medical therapy following an episode of unstable chest pain; or (c) be post-myocardial infarction or post-revascularization.

The ability of the exercise stress test to identify (or to exclude) individuals with coronary artery disease is influenced by (a) their exercise capacity (i.e., can the individual perform maximal or nearly maximal exercise?); (b) the presence of baseline electrocardiographic abnormalities (i.e., bundle-branch block or ST segment depression); (c) medications that affect the electrocardiogram or the hemodynamic response to exercise (i.e., digoxin and beta-adrenergic blocking agents, respectively); and (d) concomitant cardiac conditions that are associated with electrocardiographic abnormalities (i.e., left ventricular hypertrophy, paced rhythm, pre-excitation) (Table 17–5). Thus, patients who are unable to exercise or who have baseline ECG abnormalities require imaging (i.e., radionuclide or echocardiographic) stress testing to detect (or to exclude) coronary artery disease, since routine stress testing is unreliable in these individuals.

TABLE 17-5 Meta-Analyses of Exercise Testing

Grouping	Number of Studies	Total Number of Patients	Sens (%)	Spec (%)	Predictive Accuracy (%)
Meta-analysis of standard exercise test	147	24,047	68	77	73
Meta-analysis without MI	58	11,691	67	72	69
Meta-analysis without workup bias	3	>1000	50	90	69
Meta-analysis with ST depression	22	9153	69	70	69
Meta-analysis without ST depression	3	840	67	84	75
Meta-analysis with digoxin	15	6338	68	74	71
Meta-analysis without digoxin	9	3548	72	69	70
Meta-analysis with LVH	15	8016	68	69	68
Meta-analysis without LVH	10	1977	72	77	74

Sens indicates sensitivity; Spec, specificity; MI, myocardial infarction; and LVH, left ventricular hypertrophy.
From Gibbons RJ, Balady GJ, Bricker JT, et al. ACC/AHA 2002 guideline update for exercise testing: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Exercise Testing); 2002. American College of Cardiology Website. www.acc.org/clinical/guidelines/exercise/dirIndex.htm.

The ability of the exercise stress test to identify the presence of coronary artery disease is influenced by the pretest probability of coronary artery disease in the population tested. For example, exercise-induced ST segment depression in a 60-year-old man with typical anginal chest pain and multiple risk factors for atherosclerosis (i.e., a high pretest probability) is considered a "true positive" stress test, whereas the same findings in a 30-year-old woman with chest pain believed to be atypical for angina (i.e., a low pretest probability) is most likely to be a "false-positive" test. The relatively poor accuracy of the exercise ECG for diagnosing coronary artery disease in asymptomatic subjects has led to the recommendation that exercise testing not be used as a screening tool,[29] since false-positive tests are common among asymptomatic adults, especially women, and may lead to unnecessary testing and treatment.

The ACC and AHA have jointly developed guidelines describing the indications for exercise stress testing.[29,30]

Exercise stress testing is relatively safe, with an estimated risk of acute myocardial infarction or death of 1 per 2,500 tests. It should be supervised by a physician or a properly trained health professional working directly under the supervision of a physician, who should be in the immediate vicinity and available for emergencies. Exercise stress testing is contraindicated in subjects who are unable to exercise or who should not exercise because of physiologic or psychological limitations (Table 17–6). Although unstable angina is usually a contraindication to exercise stress testing, it can be performed safely once the patient has responded appropriately to intensive medical therapy. Exercise testing is contraindicated in patients with untreated life-threatening arrhythmias or congestive heart failure. Patients with comorbid diseases, such as chronic obstructive pulmonary disease or peripheral vascular disease, may be limited in their exercise capacity. For patients with disabilities or other medical conditions that limit their exercise capacity, pharmacologic stress testing (with dipyridamole, adenosine, or dobutamine) is an alternative (see Pharmacologic Stress Testing below).

TABLE 17-6 Contraindications to Exercise Testing

Absolute
Acute myocardial infarction (within 2 days)
High-risk unstable angina
Uncontrolled cardiac arrhythmias causing symptoms or hemodynamic compromise
Symptomatic severe aortic stenosis
Uncontrolled symptomatic heart failure
Acute pulmonary embolus or pulmonary infarction
Acute myocarditis or pericarditis
Acute aortic dissection
Relative
Left main coronary stenosis
Moderate stenotic valvular heart disease
Electrolyte abnormalities
Severe arterial hypertension
Tachyarrhythmias or bradyarrhythmias
Hypertrophic cardiomyopathy and other forms of outflow tract obstruction
Mental or physical impairment leading to inability to exercise adequately
High-degree atrioventricular block

Adapted from AHA/ACC guidelines.

Drug therapy is not routinely altered before exercise stress testing, since few data suggest that doing so improves its diagnostic accuracy. Although patients receiving a beta-adrenergic or calcium channel blocker may have a blunted increase in heart rate and blood pressure with exercise, exercise stress testing in such patients nonetheless provides information regarding exercise capacity and ischemic ECG alterations. Nitrates do not directly alter exercise capacity, but they may increase the patient's exercise capacity by preventing or relieving exercise-induced angina. Digoxin interferes with the interpretation of ST segment alterations, and patients taking it rarely manifest ST segment depression of more than 1 mm even in the face of substantial myocardial ischemia. Because of its long half-life, discontinuing digoxin immediately before the test does not ameliorate its effects.

ECHOCARDIOGRAPHY

7 Using echocardiography, one can evaluate cardiac function and structure with images produced by ultrasound. High frequency sound waves transmitted from a hand-held transducer "bounce" off tissue and are reflected back to the transducer, where the waves are collected and used to construct a real-time image of the heart.

With the exception of the ECG, echocardiography is the most frequently performed cardiovascular test. It is noninvasive, relatively inexpensive, safe, devoid of ionizing radiation, and portable, so that it can be done at the patient's bedside, in the operating room, or in the physician's office. Serial echocardiograms can be performed, especially following a cardiac procedure or a change in clinical condition, as well as to follow the progression of the underlying cardiac disease over time. It is the procedure of choice for the diagnosis and evaluation of many cardiac conditions, including valvular abnormalities, intracardiac thrombi, pericardial effusions, and congenital abnormalities. Echocardiography often is used to assess chamber sizes, function, and wall thickness. In the patient suspected of having CAD, echocardiography can be performed before, during, and immediately after exercise or pharmacologic stress (e.g., dobutamine) to evaluate the presence of ischemia-induced ventricular wall motion abnormalities.

Two approaches to echocardiography are used in clinical practice. Transthoracic echocardiography (TTE) is performed with the transducer positioned on the anterior chest wall, whereas transesophageal echocardiography (TEE) is performed with the transducer

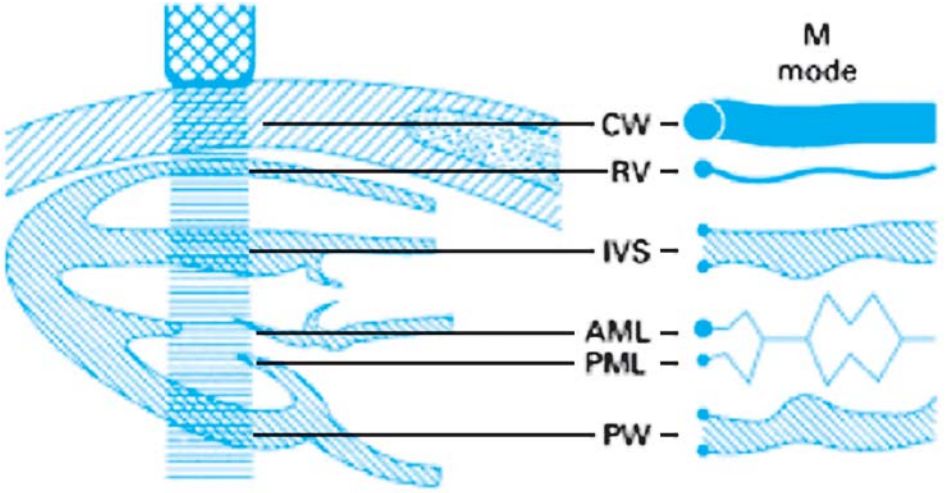

FIGURE 17-12. M-mode echocardiogram. The transducer emits an ultrasound beam, which reflects at each anatomic interface. The reflected wavefronts are detected by the probe, which records the images of cardiac structures in one plane, producing a static picture of a small region of the heart, a so-called "ice pick view." (AML, anterior mitral leaflet; CW, chest wall; IVS, interventricular septum; PML, posterior mitral leaflet; PW, posterior wall; RV, right ventricle.) *(Modified from Hagan AD, DeMaria AN. Clinical Applications of Two-Dimensional Echocardiography and Cardiac Doppler. Boston, MA: Little, Brown; 1989, with permission.) (From Fuster V. O'Rourke RA, Walsh RA, Poole-Wilson P: Hurst's The Heart, 12th ed. http://www.accessmedicine.com. Copyright © The McGraw-Hill Companies, Inc. All rights reserved.)*

positioned in the esophagus. Following transducer placement, several modes of operation are possible: M-mode (motion), two-dimensional (2D), three-dimensional (3D), and Doppler imaging.

With M-mode echocardiography, a transducer placed at a site on the anterior chest (usually along the sternal border) records the images of cardiac structures in one plane, producing a static picture of a small region of the heart, a so-called "ice pick view" (Fig. 17–12). Results depend on the exact placement of the transducer with respect to the underlying structures. Conventional M-mode echocardiography provides visualization of the right ventricle, left ventricle, and posterior left ventricular wall and pericardium. If the transducer is swept in an arc from the apex to the base of the heart, virtually the whole heart can be visualized, including the valves and left atrium.

Two-dimensional echocardiography employs multiple windows of the heart, and each view provides a wedge-shaped image (Figs. 17–13 and 17–14). These views are processed to produce a motion picture of the beating heart. When compared to M-mode echocardiography, two-dimensional echocardiography provides increased accuracy in calculating ventricular volumes, wall thickness, and the severity of valvular stenoses.

Three-dimensional echocardiography, which uses an ultrasound probe with an array of transducers and an appropriate processing system, enables a detailed assessment of cardiac anatomy and pathology, particularly valvular abnormalities as well as ventricular size and function (Fig. 17–15). The ability to "slice" the heart in an infinite number of planes in an anatomically appropriate manner and to reconstruct 3D images of anatomic structures makes this technique very powerful in understanding congenital cardiac conditions.[31]

Doppler echocardiography is used to detect the velocity and direction of blood flow by measuring the change in frequency produced when ultrasound waves are reflected from red blood cells. Color enhancement allows blood flow direction and velocity to be visualized, with different colors used for antegrade and retrograde flow. Blood flow moving toward the transducer is displayed in red, and flow moving away from the transducer is displayed in blue; increasing velocity is depicted in brighter shades of each color. Thus, with Doppler echocardiography, information regarding the presence, direction, velocity, and turbulence of blood flow can be acquired. Cardiac hemodynamic variables (e.g., intracardiac pressures) and the presence and severity of valvular disease can be assessed noninvasively with Doppler echocardiography.

When TTE is performed, the transducer is placed on the anterior chest wall, and imaging is performed in three orthogonal planes: long axis (from aortic root to apex), short axis (perpendicular to the long axis), and four-chamber (visualizing both ventricles and atria through the mitral and tricuspid valves) (Figs. 17–13 and 17–14). Sound energy is poorly transmitted through air and bone, and the ability to record adequate images is dependent on a thoracic window that gives the ultrasound beam adequate access to cardiac structures. Accordingly, in approximately 15% of subjects, suboptimal TTE images are obtained, particularly those with large lung volumes (i.e., chronic lung disease or those being ventilated mechanically) or marked obesity. In addition, TTE may not provide adequate or complete images of the posterior cardiac structures (i.e., left atrium, left atrial appendage, mitral valve, interatrial septum, descending aorta, etc.) that are located far away from the transducer.

With TEE, a flexible transducer is advanced into the esophagus and rests just behind the heart, adjacent to the left atrium and descending aorta. When compared with TTE, TEE provides more detailed images of the mitral valve, left atrium, left atrial appendage, pulmonary veins, and descending thoracic aorta. Because of the transducer's proximity to the heart, TEE allows one to delineate small cardiac structures (i.e., vegetations and thrombi <3mm in diameter) that may not be seen with TTE. As a result, TEE often is used to assess the presence of (a) mitral valve vegetations, (b) endocarditis complications (e.g., myocardial abscess), (c) left atrial appendage thrombus in the patient with a stroke or under consideration for an elective cardioversion, and (d) aortic dissection.[32–38] In addition, the transducer can be advanced into the fundus of the stomach to obtain images of the ventricles. TEE is widely utilized intraoperatively to assess the success of valve repair or replacement and to delineate cardiac anatomy in subjects with congenital heart disease at the time of surgical repair.

Although TEE is a low-risk invasive procedure, complications, such as tearing or perforation of the esophagus, esophageal burns, transient ventricular tachycardia, minor throat irritation, and transient vocal cord paralysis, occur rarely. In one series of 10,218 TEEs, 1 death (0.0098%) was reported.[39] TEE is contraindicated in patients with esophageal abnormalities, in whom passage of the transducer may be difficult or hazardous (e.g., esophageal strictures or varices).

The ACC/AHA task force has published guidelines for application of echocardiography and stress echocardiography.[35,40]

NUCLEAR CARDIOLOGY

8 Myocardial perfusion imaging, the most commonly performed nuclear cardiology procedure, is used to assess the presence, location, and severity of ischemic or infarcted myocardium. It consists of a combination of (a) some form of stress (exercise or pharmacologic), (b) administration of a radiopharmaceutical, and (c) detection of the radiopharmaceutical in the myocardium via a nuclear camera positioned adjacent to the subject's chest wall.

The most widely used radionuclides are technetium sestamibi or tetrofosmin-99m (^{99m}Tc-sestamibi or ^{99m}Tc-tetroforsmin) and thallium-201 (^{201}Tl). ^{99m}Tc is ideal for clinical imaging because it has a short half-life (about 6 hours) and can be generated in-house with a benchtop generator, thereby providing immediate availability. Because of its short half-life, repeat injections can be given to evaluate the efficacy of reperfusion therapy. ^{201}Tl has a much longer half-life (73 hours), which prevents the use of multiple doses in close temporal proximity but allows for delayed imaging following its administration. The production of ^{201}Tl requires a cyclotron. With both radiopharmaceuticals, myocardial perfusion images are obtained with a conventional gamma camera (see below).

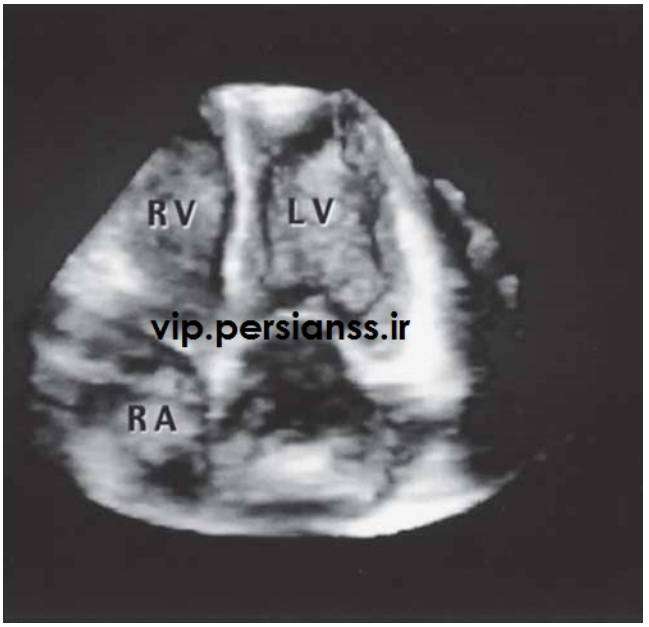

FIGURE 17-15. Real-time 3D echocardiography image, apical four-chamber plane. *(From DeMaria AN, Daniel G. Blanchard DG. Echocardiography. In: Fuster V, O'Rourke RA, Walsh RA, Poole-Wilson P: Hurst's the Heart, 12th ed. New York: McGraw-Hill, 2004:374.)*

Although both ^{99m}Tc- and ^{201}Tl-labeled compounds are useful for the detection of ischemic or infarcted myocardium, each offers certain advantages. ^{99m}Tc provides better image quality and is superior for detailed single photon emission computed tomography (SPECT) imaging (see below), whereas ^{201}Tl imaging provides superior detection of myocardial cellular viability.

With ^{201}Tl imaging, the radioisotope is injected intravenously as the patient is completing exercise or pharmacologic stress. Since thallium is a potassium analogue, it enters normal myocytes that have an active sodium-potassium ATPase pump (i.e., viable myocytes). The intracellular concentration of thallium depends on the perfusion of the tissue and its viability. In the normal heart, homogeneous distribution of thallium occurs in myocardial tissue. Conversely, regions that are scarred due to previous infarction or have stress-induced ischemia do not accumulate as much thallium as normal muscle; as a result, these areas appear as "cold" spots on the perfusion scan.

When evaluating for myocardial ischemia, an initial set of images is obtained immediately after stress and ^{201}Tl injection, and the images are examined for regions of decreased radioisotope uptake. Delayed images are obtained 3 to 4 hours later, since ^{201}Tl accumulation does not remain fixed in myocytes. Continuous redistribution of the isotope occurs across the cell membrane, with (a) differential washout rates between hypoperfused but viable myocardium and normal zones and (b) wash-in to previously hypoperfused zones. Thus, when additional images are obtained after 3 to 4 hours of redistribution, viable myocytes have similar concentrations of ^{201}Tl. Consequently, any uptake abnormalities that were caused by myocardial ischemia will have resolved (i.e, "filled in") on the delayed scan and are termed "reversible" defects, whereas those representing scarred or infarcted myocardium will persist as cold spots.

Myocardial segments that demonstrate persistent ^{201}Tl hypoperfusion with stress and redistribution imaging may represent so-called "hibernating myocardium." This markedly hypoperfused myocardium is chronically ischemic and noncontractile but metabolically active; as a result, it has the potential to regain function if perfusion is restored. Hibernating myocardium can often be differentiated from irreversibly scarred myocardium by injecting additional ^{201}Tl to enhance uptake by viable myocytes, then repeating the images 24 hours later.[41,42]

^{99m}Tc-sestamibi—also known as methoxy-isobutyl isonitrile (Tc-MIBI)—is the most widely used ^{99m}Tc-labeled compound. Similar to thallium, its uptake in the myocardium is proportional to blood flow, but its mechanism of myocyte uptake is different, in that it occurs passively, driven by the negative membrane potential. Once intracellular, it accumulates in the mitochondria, where it remains, not redistributing with the passage of time. Therefore, the myocardial distribution of sestamibi reflects perfusion at the moment of its injection. Performing a ^{99m}Tc-sestamibi procedure provides more flexibility than a ^{201}Tl procedure, in that images can be obtained for up to 4 to 6 hours after radioisotope injection and acquired again as necessary. A ^{99m}Tc-sestamibi study is usually performed as a 1-day protocol, with which an initial injection with a small tracer dose and imaging are performed at rest, after which (a few hours later) the patient undergoes a stress test, and repeat imaging is performed after injection of a larger tracer dose.

Myocardial perfusion imaging can be performed with either planar or single photon emission computed tomographic (SPECT) approaches. The planar technique consists of three 2D image acquisitions, usually for 10 to 15 minutes each. With SPECT, the camera detectors rotate around the patient in a circular or elliptical fashion, collecting a series of planar projection images at regular angular intervals (Fig. 17–16). The 3D distribution of radioactivity in the myocardium is then "reconstructed" by computer from the 2D projections. Gated SPECT is a further refinement of the process, whereby the projection images are acquired in specific phases of the cardiac cycle based on ECG triggering (so-called "gating"). With gated SPECT, myocardial perfusion and function can be evaluated.

Although stress perfusion imaging with ^{99m}Tc- or ^{201}Tl-labeled compounds offers greater sensitivity and specificity than standard exercise electrocardiography for the detection of ischemia (Fig. 17–17),[42] they are considerably more expensive and expose the patient to ionizing radiation. As a result, they should be used judiciously. Stress perfusion scans are particularly useful in patients with an underlying ECG abnormality that precludes its accurate interpretation during conventional exercise stress testing, such as patients with a bundle branch block, previous myocardial infarction, baseline ST segment abnormalities, or taking medications that affect the ST segments (e.g., digoxin).[43] When compared with standard exercise testing, nuclear perfusion imaging also provides more accurate anatomic localization of ischemia and quantitation of the extent of ischemia.[44]

Technetium Scanning

Technetium scanning is used for the evaluation of cardiac function, myocardial perfusion, and the presence of infarcted myocardium.[42,45]

Radionuclide ventriculography—so-called MUGA (multigated acquisition) scanning—is a noninvasive method for determining right and left ventricular systolic function, detecting intracardiac shunting, estimating ventricular volumes, and assessing regional wall motion. For the most part, it has been replaced by other noninvasive techniques (i.e., echocardiography and MRI) that provide similar information without ionizing radiation. Nonetheless, it may be performed in the subject in whom suitable echocardiographic images cannot be obtained or who is unable to undergo an MRI study.

During radionuclide ventriculography, ^{99m}Tc-pertechnate is introduced into the blood stream and imaged as it circulates through the heart. The resulting images of the blood pool in the

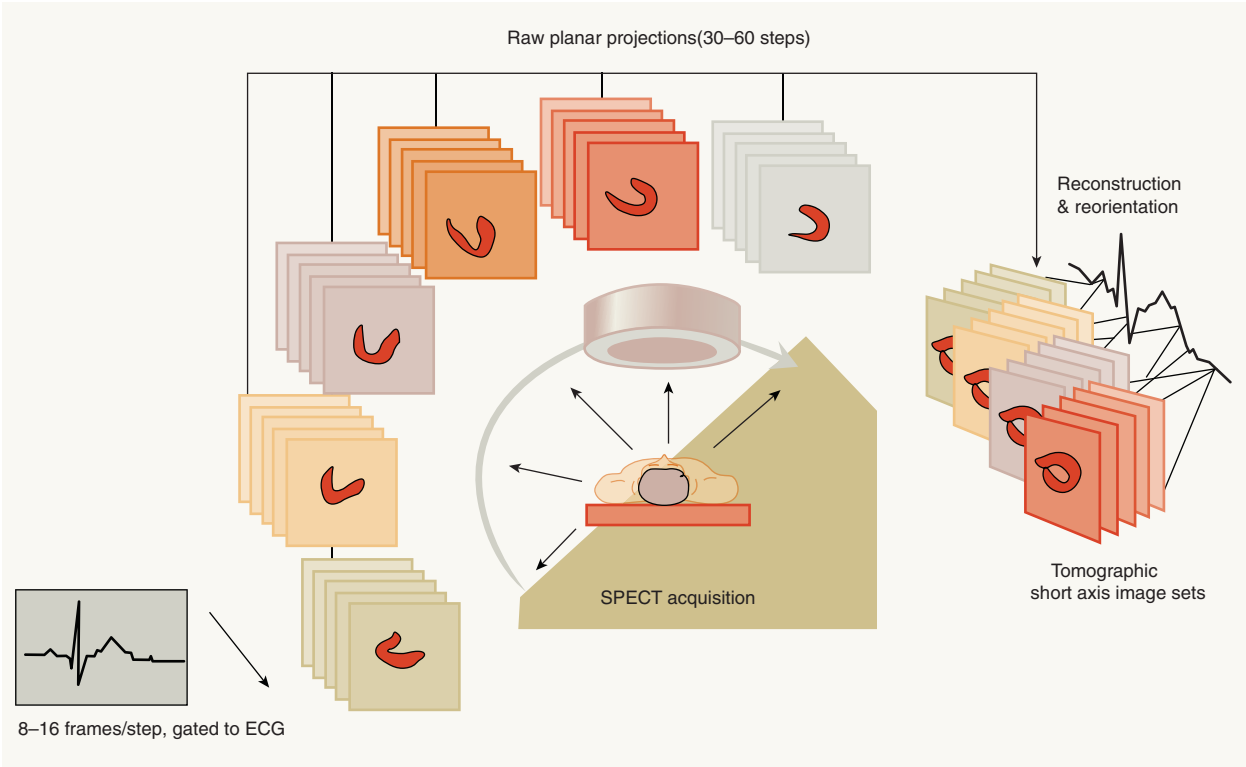

FIGURE 17-16. Schematic representation of ECG-gated SPECT imaging and acquisition. *(From Berman DS, Hachamovitch R, Shaw LJ, et al. Nuclear Cardiology. In: Fuster V, O'Rourke RA, Walsh RA, Poole-Wilson P: Hurst's the Heart, 12th ed. New York: McGraw-Hill, 2004:545.)*

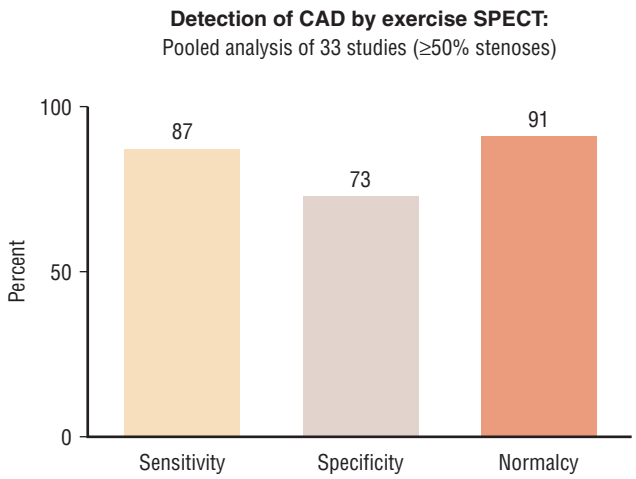

FIGURE 17-17. Detection of CAD by exercise SPECT: pooled analysis of 33 studies (≥50% stenoses). Sensitivity, specificity, and normalcy rates from a pooled analysis of 33 studies in the literature using exercise single-photon emission computed tomography (SPECT) myocardial perfusion imaging for detection of coronary artery disease (CAD). Note that the normalcy rate, which is derived from the percentage of patients with normal scans who have <5% pretest likelihood of CAD is shown. This normalcy rate of 91% is significantly higher than specificity. *(Reprinted from J Am Coll Cardiol, Vol. 42, Klocke FJ, Baird MG, Bateman TM, et al, ACC/AHA/ASNC guidelines for the clinical use of cardiac radionuclide imaging—executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (ACC/AHA/ASNC Committee to Revise the 1995 Guidelines for the Clinical Use of Radionuclide Imaging), pages 1318–1333, Copyright © 2003, with permission from Elsevier.)*

cardiac chambers are analyzed by computer to calculate right and left ventricular ejection fractions.

The radioactive marker can be introduced to the patient's blood in vivo or in vitro. With the in vivo method, stannous (tin) ions are injected intravenously, after which an intravenous injection of ^{99m}Tc-pertechnate labels the red blood cells in vivo. With the in vitro method, an aliquot of the patient's blood is withdrawn, to which the stannous ions and ^{99m}Tc-pertechnate are added, after which the labeled blood is reinfused into the patient. The stannous chloride is given to prevent the technetium from leaking from the red blood cells.

Once the radiolabeled red blood cells are circulating, the patient is placed under a gamma camera, which detects the radioactive ^{99m}Tc. As the images are acquired, the patient's heart beat is used to "gate" the acquisition, resulting in a series of images of the heart at various stages of the cardiac cycle.

Depending on the objectives of the test, the operator may decide to perform a resting or a stress MUGA. During the resting MUGA, the patient lies stationary, whereas during a stress MUGA, the patient is asked to exercise on a supine bicycle ergometer as images are acquired. The stress MUGA allows the operator to assess cardiac performance at rest and during exercise. It is usually performed to assess the presence of suspected coronary artery disease.

Infarct-avid radionuclides, such as technetium-pyrophosphate (^{99m}Tc-PYP), are used to assess the presence and extent of infarcted myocardium. Since ^{99m}Tc-PYP binds to calcium that is deposited in the infarcted area, it is known as *hot-spot scanning*. Hot spots appear where necrotic myocardial tissue is present, which may occur with recent myocardial infarction, myocarditis, myocardial abscesses, and myocardial trauma. Additionally, ^{99m}Tc-PYP uptake has been observed on occasion in patients with unstable angina, severe diabetes mellitus, and cardiac amyloidosis.

Uptake of ^{99m}Tc-PYP by necrotic myocardium is first detectable about 12 hours after the onset of myocardial infarction, with a peak intensity of ^{99m}Tc-PYP at 48 hours. Washout occurs over 5 to 7 days, so ^{99m}Tc-PYP is a useful late marker of infarction, especially in the patient suspected of having a painless (e.g., "silent") infarction.

Pharmacologic Stress Testing

9 In the patient undergoing myocardial perfusion imaging for the evaluation of coronary artery disease, exercise stress is preferred over pharmacologic stress, since it allows an assessment of the patient's exercise capacity, symptoms, ST segment changes, and level of exertion that results in ischemia.[44] In the individual who is unable to exercise adequately (because of orthopedic limitations or inability to ambulate), a pharmacologic stress test can be performed in conjunction with various imaging modalities, such as thallium planar scanning, SPECT, MRI, or echocardiography.[42–44]

Vasodilator Stress Testing The vasodilators, dipyridamole and adenosine, are the preferred pharmacologic stress agents for myocardial perfusion imaging. Following the administration of one of these, blood flow increases 3- to 5-fold in undiseased coronary arteries and minimally, or not at all, in arteries with flow-limiting stenoses. Since radioisotope uptake by the myocardium is directly related to coronary blood flow, the region of myocardium perfused by an artery with a flow-limiting stenosis appears as a "cold spot" on the nuclear perfusion scan following vasodilator administration.

Adenosine dilates coronary arteries by binding to specific adenosine receptors on smooth muscle cells in the coronary arterial media. Dipyridamole causes coronary vasodilatation by blocking the cellular uptake of adenosine, thereby increasing the extracellular adenosine concentration. Currently, adenosine is used more often than dipyridamole because of its rapid onset and termination of action. Since methylxanthines (i.e., caffeine and theophylline) block adenosine binding and can interfere with the vasodilatory effects of these agents, foods and beverages containing caffeine should not be ingested during the 24 hours before their administration.

During a vasodilator stress test, the patient normally manifests a modest increase in heart rate, a fall in blood pressure, and no or minimal electrocardiographic changes. Chest pain, shortness of breath, flushing, and dizziness occur commonly during vasodilator administration. As a result, the hemodynamic, electrocardiographic, and symptomatic responses to vasodilator administration do not provide insight into the presence or absence of coronary artery disease.

Dipyridamole is administered intravenously at 0.142 mg/kg/min for 4 minutes, with the maximal effect occurring 3 to 4 minutes after the infusion has ended. Adenosine is administered intravenously at 0.140 mcg/kg/min for 6 minutes, with the maximum effect occurring 30 seconds after the infusion is completed. At the end of the dipyridamole infusion or 3 minutes after initiation of adenosine infusion, thallium is administered, after which nuclear imaging follows immediately and can be repeated 24 hours later to distinguish scarred from hibernating myocardium.

Since these agents may induce severe bronchospasm in subjects with a history of asthma, they should not be administered to such individuals. With adenosine, advanced atrioventricular block may occur. Fortunately, severe side effects are rare, occurring in only 1 in 10,000 patients receiving these agents, and are usually reversed with intravenous aminophylline 75 to 125 mg.

In the patient referred for stress testing to assess the presence of CAD, pharmacologic stress is indicated for those unable or with a contraindication to exercise. This includes patients with (a) a chronic debilitating illness, such as COPD, liver, or kidney disease; (b) older age and decreased functional capacity; (c) limited exercise capacity due to injury, arthritis, orthopedic problems, neurologic disorders, myopathic diseases, or peripheral vascular disease; (d) an acute coronary syndrome; (e) postoperative state; and (f) beta-blocker or other negative chronotropic agents that interfere with the subject's ability to achieve an adequate increase in heart rate in response to exercise.

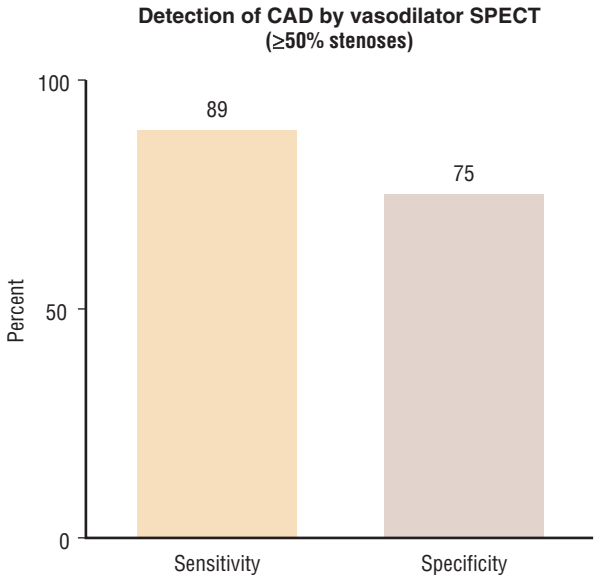

FIGURE 17-18. Detection of CAD by vasodilator SPECT (≥50% stenoses). Sensitivity and specificity for detection of coronary artery disease (CAD) by vasodilator stress. The definition of a significant lesion was ≥50% stenosis by coronary angiography. These data represent a pooled analysis from the literature. (SPECT, single-photon emission computed tomography.) *(Reprinted from J Am Coll Cardiol, Vol. 42, Klocke FJ, Baird MG, Bateman TM, et al, ACC/AHA/ASNC guidelines for the clinical use of cardiac radionuclide imaging—executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (ACC/AHA/ASNC Committee to Revise the 1995 Guidelines for the Clinical Use of Radionuclide Imaging), pages 1318–1333, Copyright © 2003, with permission from Elsevier.)*

Pharmacologic stress testing has a similar sensitivity and specificity to exercise stress testing (Fig. 17–18). In an analysis of 17 studies of almost 2000 patients, pharmacologic stress testing had a sensitivity of 89% and a specificity of 75% for detecting ischemic heart disease.[42] As with routine stress testing, the sensitivity and specificity are affected by the prevalence and pretest likelihood of coronary artery disease in the population studied.

Dobutamine Stress Testing The patient who is not a candidate for vasodilator stress testing (because of a history of bronchospasm, advanced atrioventricular block, or recent caffeine ingestion) or does not desire infusion of a radiopharmaceutical may undergo a dobutamine stress test with echocardiographic imaging. Dobutamine, a synthetic catecholamine, is an inotropic agent that increases heart rate and myocardial contractility, thereby increasing myocardial oxygen demands. In regions of the heart where myocardial oxygen supply is insufficient to meet the increase in demands (because of a flow-limiting stenosis in the coronary artery supplying that region), ischemia develops and causes regional abnormalities in contraction that may be observed with echocardiography.

When used for stress testing, dobutamine is infused intravenously at 10 mcg/kg/min, with the dose increased at 3-minute intervals in increments of 10 mcg/kg/min to a maximum of 40 mcg/kg/min. To achieve a further increase in myocardial oxygen demands, atropine (0.5 to 1 mg) may be injected to augment the dobutamine-induced increase in heart rate, and handgrip exercise may be performed concomitantly to achieve an increase in blood pressure. The ECG and blood pressure are monitored throughout the test, and echocardiographic images are

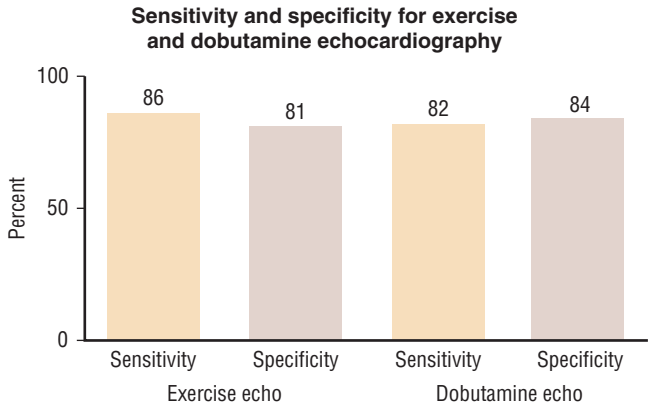

FIGURE 17-19. Sensitivity and specificity for exercise and dobutamine echocardiography. Note a slightly higher sensitivity for exercise echo compared to dobutamine echo. *(Reprinted from J Am Coll Cardiol, Vol. 42, Cheitlin MD, Armstrong WF, Aurigemma GP, et al. ACC/AHA/ASE 2003 guideline update for the clinical application of echocardiography–summary article: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (ACC/AHA/ASE Committee to Update the 1997 Guidelines for the Clinical Application of Echocardiography), pages 954–970, Copyright © 2003, with permission from Elsevier.)*

obtained during the last minute of each dobutamine dose infusion and during recovery. For the patient with suboptimal echocardiographic images, dobutamine stress testing may be combined with radionuclide perfusion imaging, in which case, thallium is injected 2 to 3 minutes before completion of the dobutamine infusion.

Since beta-blocker and calcium channel blocker therapy may interfere with the heart rate response to dobutamine, it is recommended that they be discontinued before the test. Dobutamine stress testing is relatively well tolerated, with ventricular irritability occurring rarely (0.05%). The dobutamine infusion is discontinued with the appearance of severe chest pain, extensive new wall motion abnormalities, substantial ST segment changes suggestive of severe ischemia, tachyarrhythmias, or a symptomatic fall in systemic arterial pressure. Beta-blockers can be used to reverse most adverse effects if they persist. Dobutamine stress testing is contraindicated in patients with aortic stenosis, uncontrolled hypertension, and severe ventricular arrhythmias.

A review of 37 studies of 3,280 patients reported that dobutamine stress testing had a sensitivity of 82% and a specificity of 84% for detecting coronary artery disease (Fig. 17–19). The sensitivity was highest in subjects with three vessel coronary artery disease (92%).[46]

COMPUTED TOMOGRAPHY

Computed tomographic (CT) scanning is becoming increasingly popular as a primary screening procedure in the evaluation of individuals with suspected or known CVD, since it provides similar information as other diagnostic modalities, such as catheterization and echocardiography, yet it is less invasive than the former.[47–49] In recent years, technologic advances have enhanced CT's definition and spatial resolution of cardiac structures, such as coronary arteries, valves, pericardium, and cardiac masses. In addition, CT provides an accurate measurement of chamber volumes and sizes as well as wall thickness.

CT scanners produce images by rotating an x-ray beam around a circular gantry (e.g., opening), through which the patient advances on a moving couch. Two types of CT scanners are used for cardiac imaging: electron beam computed tomography (EBCT) and mechanical CT.[49] With EBCT, the electron x-ray tube remains stationary, and the electron beam is swept electronically around the patient. With mechanical or conventional CT, the x-ray tube itself rotates around the patient, and the use of multirow detector systems rays (i.e., multislice CT) allows acquisition of up to 256 simultaneous images, each 0.5 mm in thickness. With either type of CT, the image acquisition is gated to the ECG to minimize radiation exposure, and cardiac images are obtained at end inspiration (i.e., during a breath hold) to minimize artifact caused by cardiac motion.

Since EBCT has no moving parts, it requires a shorter image acquisition time and exposes the patient to less radiation when compared with conventional CT (<1.0 rad vs 15 rads, respectively). With EBCT, image resolution is sufficient to assess global and regional ventricular function and coronary anatomy, but it is not sufficient to provide an accurate assessment of the presence and severity of coronary artery disease. However, it can reliably detect the presence and extent of coronary arterial calcification, which is expressed as a coronary artery calcium score in Agatston units (Fig. 17–20). Although the presence of coronary arterial calcification correlates with the total atherosclerotic plaque burden in epicardial coronary arteries, it does not predict the presence or location of flow-limiting (>50% luminal diameter narrowing) coronary arterial stenoses, nor does the lack of coronary calcium exclude the presence of atherosclerotic plaque.[47–49]

The distribution of calcification scores in populations of individuals without known heart disease has been studied extensively. These studies have shown that the amount of coronary arterial calcification increases with age, and men typically develop calcification 10 to 15 years earlier than women.[49] In the majority of asymptomatic men over 55 years of age and women over 65 years of age, coronary arterial calcification is detectable. The person who undergoes coronary calcium screening with EBCT receives a score in Agatston units as well as a calcium score percentile with which his/her score is compared to a population of subjects of similar age and gender.

Unlike EBCT, multislice CT has sufficient resolution to visualize the coronary arteries (Fig. 17–21). To accomplish this, radiographic contrast material is administered intravenously, and a beta-blocker is given to slow the heart rate to <70 beats/min to minimize motion artifact. Compared with conventional coronary angiography, cardiac CT has a sensitivity of 85%, a specificity of 90%, a positive predictive value of 91%, and a negative predictive value of 83% for detecting or excluding a coronary arterial stenosis of 50% or more luminal diameter narrowing.[50] It has limited diagnostic utility in patients with extensive coronary arterial calcification or a rapid heart rate, due to artifacts caused by high-density calcified coronary arterial stenoses or cardiac motion. Vessels with a luminal diameter <1.5mm cannot be assessed reliably with cardiac CT, since the resolution is insufficient.

Independent of its use in assessing coronary arteries, cardiac CT often is used in the subject with suspected aortic dissection, in whom its accuracy in detecting dissection is >90%. In the patient with possible constrictive pericarditis, the pericardium can be evaluated for thickening and calcification. In the patient with a possible cardiac mass, CT scanning allows one to assess the size and location of the mass, and tissue density differentiation may aid in its characterization. Cardiac CT can be used to calculate left ventricular volumes, ejection fraction, and mass, and these measurements obtained with CT scanning are superior in accuracy and reproducibility to those obtained with angiography or echocardiography. CT scans allow visualization of congenital heart defects. Although MRI may provide similar information without exposing the patient to ionizing radiation, many patients have contraindications to MRI (i.e., those with an implanted metallic device). In such patients, cardiac CT is an alternative method for visualizing cardiac anatomy.

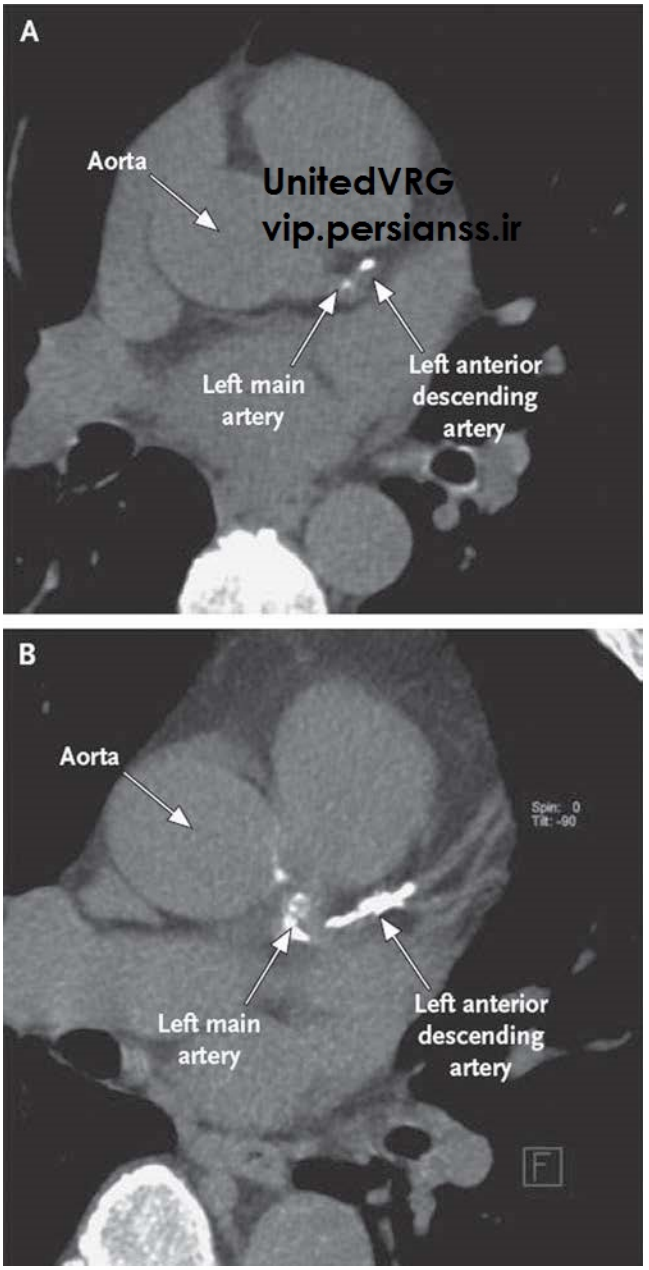

FIGURE 17-20. CT scans of the left coronary artery in two asymptomatic men. Two asymptomatic men, 51 years of age and 81 years of age, underwent coronary-artery calcium (CAC) imaging with multidetector CT. There is calcification of the left main and proximal left anterior descending coronary arteries in both the younger patient (*panel A*) and the older patient (*panel B*). The CAC score for the younger man, although relatively low at 80, places him in the 85th percentile for severity of CAC for men in his age group. The older man's CAC score is higher, at 1,054, but the severity of his CAC relative to that for men in his age group is lower—in the 70th percentile. *(Bonow RO. Should Coronary Calcium Screening Be Used in Cardiovascular Prevention Strategies? N Engl J Med 2009;361:990–997. Copyright © 2009 Massachusetts Medical Society. All rights reserved.)*

Roles of Nuclear Cardiology, Cardiac Computed Tomography, and Cardiac Magnetic Resonance: Assessment of Patients with Suspected Coronary Artery Disease. J Nucl Med 2006;47:74–82.)*

POSITRON EMISSION TOMOGRAPHY

Positron emission tomography (PET) is a relatively new modality for diagnostic imaging in patients with suspected or known CVD. Among imaging techniques, it is unique in its ability (a) to provide quantitative imaging with high temporal resolution; (b) to image a large number of physiologically active radiotracers; and (c) to apply tracer kinetic principles so that in vivo imaging can be performed. With PET, myocardial metabolic activity, perfusion, and viability can be assessed.[41,42] Using appropriate positron-emitting biologically active tracers, PET can measure regional myocardial uptake of exogenous glucose and fatty acids, quantitate free fatty acid metabolism, ascertain myocardial energy substrates, and evaluate myocardial chemoreceptor sites.

In the fasting state (i.e., low serum glucose and insulin concentrations), fatty acids are the preferred energy source of the myocardium. Following the ingestion of carbohydrate, serum glucose and insulin concentrations increase, and glucose becomes the preferred myocardial fuel. Glucose also is the major myocardial fuel during ischemia, since ischemia impairs mitochondrial fatty acid oxidation. Using positron-emitting isotopes, such as oxygen-15 (^{15}O-oxygen), carbon-11 (^{11}C-palmitate or ^{11}C acetate), and fluoride-18 (^{18}F-fluorodeoxyglucose), myocardial oxygen consumption and substrate utilization can be measured, from which ischemic and nonischemic regions of the heart can be identified.[41] PET usually is used in conjunction with pharmacologic stress testing to provoke ischemia, with images obtained before and after stress.

Tracers such as rubidium 82 (^{82}Rb) and nitrogen 13 (^{13}N) are retained in the myocardium in proportion to blood flow. PET imaging with these agents allows one to measure myocardial blood flow at rest and during pharmacologically induced hyperemia. Thus, PET can be used to assess the physiologic significance of coronary arterial stenoses, which is useful when attempting to determine if a luminal diameter narrowing of intermediate severity (50%–70%) is causing ischemia.

In the patient with noncontractile myocardium, PET is considered to be the "gold standard" technique for distinguishing infarcted myocardium from chronically ischemic, metabolically active myocardium that has the potential to regain function if perfusion is restored (hibernating myocardium).[41] Myocardial infarction and ischemia can be distinguished by analysis of PET images of the glucose analog ^{8}F-fluorodeoxyglucose (FDG), which is injected after glucose administration, and the perfusion

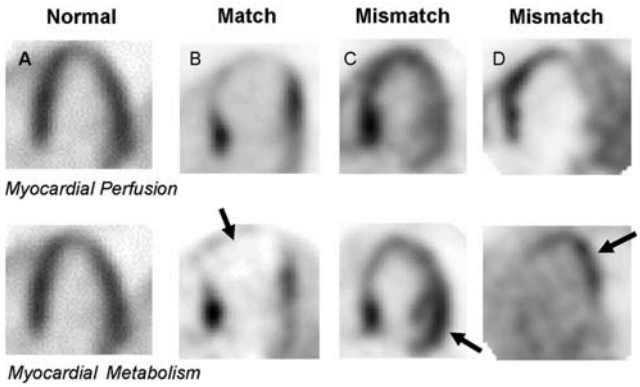

FIGURE 17-22. Patterns of myocardial perfusion (*upper panel*) and metabolism (with ^{18}F-FDG; *lower panel*). **A.** Normal myocardial perfusion and metabolism. **B.** Severely reduced myocardial perfusion in the anterior wall associated with a concordant reduction in ^{18}F-FDG uptake (arrow), corresponding to a match. **C.** Mildly reduced perfusion in the lateral and posterior lateral wall associated with a segmental increase in glucose metabolism (mismatch). **D.** Severely reduced myocardial perfusion in the lateral wall with a segmental increase in ^{18}F-FDG uptake (arrow), reflecting a perfusion metabolism mismatch. *(From Schelbert HR. Positron Emission Tomography for the Noninvasive Study and Quantitation of Myocardial Blood Flow and Metabolism in Cardiovascular Disease. In: Fuster V, O'Rourke RA, Walsh RA, Poole-Wilson P: Hurst's the Heart, 12th ed. New York: McGraw-Hill, 2004:675.)*

tracer ^{13}N-ammonia. Regions that show a concordant reduction in myocardial blood flow and FDG uptake ("flow-metabolism match") are considered to be irreversibly injured, whereas regions in which FDG uptake is relatively preserved or increased despite a perfusion defect ("flow-metabolism mismatch") are considered to be ischemic (Fig. 17–22). This approach more accurately predicts recovery of regional function after revascularization than does SPECT imaging. The magnitude of improvement in heart failure symptoms after revascularization in patients with left ventricular dysfunction correlates with the preoperative extent of FDG "mismatch."[51]

The main strengths of PET compared with SPECT are its superior spatial resolution and ability to assess myocardial viability accurately.[41,42] The limited availability of PET scanners and the need for a cyclotron on site are its main limitations. Recently, the number of PET scanners has increased to approximately 1,200 in the United States and 400 in Europe. In the United States, more than 150,000 cardiac PET scans are performed annually, of which about 68,000 are viability and about 86,000 are perfusion scans.[41]

CARDIAC CATHETERIZATION AND ANGIOGRAPHY

6 Cardiac catheterization plays a pivotal role in the evaluation of patients with suspected or known cardiac disease; in addition, it has become an important therapeutic alternative to cardiac surgery in many patients who require nonmedical therapy.

Indications

Diagnostic cardiac catheterization is appropriate under several conditions. First, it is often performed to confirm or to exclude the presence of a cardiac condition that is suspected from the patient's history, physical examination, or noninvasive evaluation. In such a circumstance, it allows an assessment of the presence and severity of cardiac disease. For example, in a subject with progressive angina pectoris or a positive exercise stress test, coronary angiography allows the physician to visualize the coronary arteries sufficiently to assess the presence and extent of coronary artery disease. Second, catheterization is often helpful in the patient with a confusing or difficult clinical presentation in whom the noninvasive evaluation is inconclusive. For instance, a hemodynamic evaluation or coronary angiography may be useful in the patient with unexplained dyspnea. Third, data obtained at catheterization may provide prognostic information that is helpful in guiding therapy. Such is the case, for example, in the patient with cardiomyopathy, in whom the hemodynamic data obtained at catheterization are used to guide medical therapy and to assess the need for and timing of cardiac transplantation.

TABLE 17-7 Relative Contraindications to Cardiac Catheterization

Decompensated heart failure (e.g., pulmonary edema)
Uncontrolled ventricular irritability
Uncontrolled systemic arterial hypertension
Acute or severe renal insufficiency
Difficulty with vascular access
Electrolyte imbalance (i.e., hypo- or hyperkalemia)
Digitalis intoxication
Active infection or febrile illness
Uncorrected bleeding diathesis
Severe anemia
Active bleeding from internal organ
Severe allergy to radiographic contrast material
Mental incompetence

Contraindications

The only absolute contraindication to catheterization is the refusal of a mentally competent patient to provide informed consent. Relative contraindications (Table 17–7) mostly involve conditions in which the risks of the procedure are increased or the information obtained from it is potentially unreliable. In these circumstances, the benefits of having the data that are obtained at catheterization must be weighed against the procedure's increased risks. Catheterization usually is not performed in the patient who refuses therapy for the condition for which diagnostic catheterization is recommended.

Complications

Because catheterization is an invasive procedure, its performance is associated with major and minor risks. The incidence of a major complication (death, myocardial infarction, or cerebrovascular accident) during or within 24 hours of diagnostic catheterization is 0.2% to 0.3%. Deaths, which occur in 0.1 to 0.2% of patients, may be caused by perforation of the heart or great vessels, cardiac arrhythmias, acute myocardial infarction, or anaphylaxis to radiographic contrast material.

Numerous minor complications may cause morbidity but exert no effect on mortality. Local vascular complications occur in 0.5% to 1.5% of patients. The injection of radiographic contrast material occasionally is associated with allergic reactions of varying severity, and a rare individual has anaphylaxis. Of patients with a known allergy to contrast material, only about 15% have an adverse reaction with its repeat administration, and most of these reactions are minor (e.g., urticaria, nausea, vomiting). In most patients with a previous allergic reaction to radiographic contrast material, angiography can be performed safely, but premedication with glucocorticosteroids and antihistamines and the use of a different contrast material are usually recommended. Use of excessive quantities of radiographic contrast material may result in renal insufficiency, particularly in patients with preexisting renal dysfunction and diabetes mellitus.

Techniques

Cardiac catheterization is generally performed with the patient in the fasting state and mildly sedated. Anticoagulants are discontinued before the procedure (warfarin for several days, heparin for 4–6 hours). Cardiac catheterization requires vascular access, which is usually obtained percutaneously via the femoral, brachial, or radial vessels.

With the *percutaneous approach,* the area overlying the vessel is aseptically prepared and locally anesthetized. The vessel is punctured with a needle, through which a flexible metal wire is advanced into the vessel's lumen, over which a sheath with a sideport extension is advanced into the vessel. The sideport extension allows continuous monitoring of arterial pressure (through an arterial sheath) or infusion of fluids (through a venous sheath) as catheters are advanced through the sheath to the heart. When the procedure is completed, the catheters and sheaths are removed, after which local pressure is applied or a closure device is used to achieve hemostasis. If the femoral approach is used, the patient remains at bed rest for 2 to 8 hours to minimize the chance of hemorrhage. With the radial and brachial approach, bed rest following sheath removal is not necessary.

During routine right heart catheterization, measurements of pressures and blood oxygen saturations in the vena cavae, right atrium, right ventricle, pulmonary artery, and pulmonary capillary wedge position can be performed, and cardiac output can be quantified (Table 17–8 lists normal values). The measurement of right-sided pressures helps the physician to evaluate the severity of tricuspid or pulmonic stenosis, to assess the presence and severity of pulmonary hypertension, and to calculate pulmonary vascular resistance. In the absence of pulmonary vein stenosis (a rare condition), the pulmonary capillary wedge pressure accurately reflects the left atrial pressure. Occasionally angiography is performed to define right-sided anatomic abnormalities or to evaluate the severity of right-sided valvular regurgitation.

With left heart catheterization, mitral and aortic valvular function, left ventricular pressures and function, systemic vascular resistance, and coronary arterial anatomy can be assessed. To perform angiography or to measure the pressure in the left ventricle, a catheter is usually advanced retrograde across the aortic valve.

TABLE 17-8 Normal Hemodynamic Values

Measurement	Value
Flows	
Cardiac index (L/min/m^2)	2.6–4.2
Stroke volume index (mL/m^2)	35–55
Pressures (mm Hg)	
Aorta/systemic artery	
Peak systolic/end-diastolic	100–140/60–90
Mean	70–105
Left ventricle	
Peak systolic/end-diastolic	100–140/3–12
Left atrium (PCW)	
Mean	1–10
a wave	3–15
v wave	3–15
Pulmonary artery	
Peak systolic/end-diastolic	16–30/4–12
Mean	10–16
Right ventricle	
Peak systolic/end-diastolic	16–30/0–8
Right atrium	
Mean	0–8
a wave	2–10
v wave	2–10
Resistances	
Systemic vascular resistance	
Wood units	10–20
dynes-sec-cm^{-5}	770–1,500
Pulmonary vascular resistance	
Wood units	0.25–1.5
dynes-sec-cm^{-5}	20–120
Oxygen Consumption (mL/min/m^2)	110–150
AV O_2 Difference (mL/dL)	3.0–4.5

AV, arteriovenous; PCW, pulmonary capillary wedge.

Hemodynamic Measurements

Cardiac Output The blood flow measurement most often performed during catheterization is the quantitation of cardiac output. This variable allows assessment of overall cardiovascular function, vascular resistances, valve orifice areas, and valvular regurgitation. In the catheterization laboratory, the three common methods of measuring cardiac output are the Fick principle, the indicator dilution technique, and angiography.

Fick Principle

The Fick principle is based on the fact that when a substance is consumed by an organ, its concentration is the product of blood flow to the organ and the substance's arteriovenous difference across the organ. Using the lungs as the organ of interest and oxygen as the substance, one can calculate pulmonary blood flow (e.g., cardiac output) using the formula:

$$\text{Cardiac output (L/min)} = \text{Oxygen consumption (mL/min)} / \text{Arteriovenous oxygen difference (mL/L)}$$

Oxygen consumption is measured by analyzing the patient's exhaled air, and the arteriovenous oxygen difference is calculated by measuring the oxygen content in a blood sample procured from the aorta and the pulmonary artery.

Dilution Method

With indicator dilution, a known amount of indicator is injected as a bolus into the circulation and allowed to mix completely in the blood, after which its concentration is measured. A time-concentration curve is generated, and a minicomputer calculates the cardiac output from the area of the inscribed curve. The most widely used indicator for the measurement of cardiac output is cold solution. A balloon-tipped, flow-directed, polyvinyl chloride catheter (a so-called Swan-Ganz catheter) with a thermistor at its tip and an opening 25 to 30 cm proximal to the tip is inserted into a vein and advanced to the pulmonary artery, so that the proximal opening is located in the vena cavae or right atrium and the thermistor is in the pulmonary artery. A known amount of cold fluid is injected through the proximal port; it mixes completely in the right ventricle and causes a change in blood temperature, which is detected by the thermistor. The thermodilution method is relatively inexpensive and easy to perform and does not require arterial sampling or blood withdrawal.

Angiographic Method

From the left ventriculogram, the volume of blood ejected with each heartbeat (stroke volume) can be determined. It is then multiplied by the heart rate, yielding the angiographic cardiac output. The measurement of cardiac output by the angiographic method is potentially erroneous in patients with extensive segmental wall motion abnormalities or misshapen ventricles, in whom the determination of stroke volume may be inaccurate.

Pressures

One of the most important functions of cardiac catheterization is to measure and to record intracardiac pressures. Once a catheter is positioned in a cardiac chamber, it is connected through fluid-filled, stiff, plastic tubing to a pressure transducer, which transforms the pressure signal into an electrical signal that is recorded. During catheterization, pressures are usually measured directly from each of the cardiac chambers: right atrium, right ventricle, pulmonary artery, ascending aorta, and left ventricle. Because the left atrial pressure is transmitted to the pulmonary capillaries, it can be recorded "indirectly" as the pulmonary capillary "wedge" pressure. In addition to measuring pressures from each cardiac chamber, pressures from certain chambers are examined simultaneously to identify or to exclude a gradient between them indicative of valvular stenosis.

Resistances

The resistance of a vascular bed is calculated by dividing the pressure gradient across the bed by the blood flow through it. Thus,

Systemic vascular resistance = (Mean systemic arterial pressure – mean right atrial pressure)/Sytemic blood flow

and

Pulmonary vascular resistance = (Mean Pulmonary arterial pressure – mean left atrial pressure)/Pulmonary blood flow

Because a properly obtained pulmonary capillary wedge pressure is similar to left atrial pressure, it can be substituted for it in the above equation. These formulae express resistances in arbitrary resistance units. Most often, these values are multiplied by 80 to express them in metric units of dynes-sec-cm^{-5}. Normal values are displayed in Table 17–8.

An elevated systemic vascular resistance is often present in the patient with systemic arterial hypertension. It may also be observed in patients with a reduced forward cardiac output and compensatory arteriolar vasoconstriction (often seen in patients with heart failure). Conversely, systemic vascular resistance may be reduced in patients with arteriolar vasodilation (due, for example, to sepsis) or those with an increased cardiac output (due, for example, to an arteriovenous fistula, severe anemia, fever, or thyrotoxicosis). An elevated pulmonary vascular resistance often is observed in patients with primary lung disease, pulmonary vascular disease, and a greatly elevated pulmonary venous pressure resulting from left-sided myocardial or valvular dysfunction.

ANGIOGRAPHY

During angiography, radiographic contrast material is injected into the cardiovascular structure of interest, and the images are digitally recorded and stored on a computer-accessible medium (i.e., CD-ROM, DVD, external memory drives, etc.). The resultant angiogram permits the study of cardiac structures in real time, in slow motion, or by single frame.

Left Ventriculography

With angiography of the left ventricle, global and segmental left ventricular function, left ventricular volumes and ejection fraction, and the presence and severity of mitral regurgitation can be assessed. A segment of the left ventricular wall with reduced systolic motion is said to be hypokinetic; a segment that does not move is akinetic; and a segment that moves paradoxically during systole is dyskinetic.

Coronary Angiography

Selective coronary angiography is usually performed to determine the presence and severity of fixed, atherosclerotic coronary artery disease and to guide subsequent percutaneous (e.g., angioplasty with or without stent placement) or surgical (e.g., bypass grafting) therapy. Under fluoroscopic guidance, the ostia of the native right and left coronary arteries or bypass grafts are engaged selectively with a catheter, and radiographic contrast material is injected manually during digital image recording. Because atherosclerotic coronary arterial stenoses are often eccentric and the coronary vessels often overlap one another, images are obtained in multiple obliquities, thereby ensuring a complete angiographic assessment of each arterial segment.

Coronary angiography provides radiographic images of the coronary lumina but does not visualize the actual arterial walls. A stenosis is present when a discrete reduction in luminal diameter is noted, and its severity is assessed by comparing it with presumably normal adjacent segments of the same artery. Thus, if atherosclerosis is diffuse and involves the entire artery, angiography may lead to an underestimation of the severity of disease.

Aortography

Aortography is accomplished with the rapid injection of radiographic contrast material into the aorta. With proximal aortography, the severity of aortic valve regurgitation, the location of saphenous vein bypass grafts, and the anatomy of the proximal aorta and its branches can be assessed. Distal aortography usually is performed to assess the presence of vascular abnormalities, such as aneurysm, dissection, intraluminal thrombus, or branch vessel stenosis.

Valvular Stenosis or Regurgitation

In patients with valvular stenosis, the effective valve orifice area can be calculated with data obtained during catheterization using principles of standard fluid dynamics. The pressures on either side of a stenotic valve are recorded simultaneously and the flow across it is measured, after which the valve area is calculated.

The presence and severity of valvular regurgitation may be evaluated qualitatively by observing the amount of radiographic contrast material that regurgitates in a retrograde direction across the valve. The magnitude of regurgitation is estimated as trivial (1+), mild (2+), moderate (3+), or severe (4+).

Endomyocardial Biopsy

Through a long sheath positioned across the tricuspid valve, a bioptome can be advanced to obtain small pieces (1–2 mm^2) of myocardial tissue from the right ventricular side of the interventricular septum. Endomyocardial biopsy is used most often to detect transplant rejection and to monitor immunosuppressive therapy in survivors of cardiac transplantation. Less commonly, it is undertaken in the patient with suspected infiltrative cardiomyopathy or active inflammation of the heart (e.g., myocarditis). In experienced hands, complications are uncommon: cardiac perforation occurs in only 0.3% to 0.5%, and the procedure-related mortality is only 0.05%.

INTRAVASCULAR ULTRASOUND

Intravascular ultrasound (IVUS) employs a small catheter-mounted ultrasound transducer to provide detailed images of the coronary arterial lumen. In contrast to coronary angiography, which does not visualize the actual arterial wall, IVUS provides quantitative information from within the vessel regarding vessel diameter, circumference, luminal diameter, plaque volume, and percent narrowing. Qualitative information regarding the amount of plaque stenosis, plaque composition (e.g., calcific, fibrous, or fatty plaque), and the presence of plaque versus thrombus, thrombus versus tumor, and aneurysm and hematoma can be provided by IVUS. IVUS is used as a therapeutic adjunct to PTCA, atherectomy, stent or graft

placement, and fibrinolysis, although its routine use with these modalities may not be justified. These combination procedures may be monitored in real time as the procedure (e.g., atherectomy) is being performed. In recent studies, IVUS has been helpful in the evaluation of the progression or regression of atherosclerosis. Current trials are testing medications for atherosclerosis regression and changes in plaque morphology.

Intravascular optical coherence tomography provides high-resolution, cross-sectional images of tissue with an axial resolution of 10 microns and a lateral resolution of 20 microns.[63] Optical coherence tomographic images of human coronary atherosclerotic plaques are much more structurally detailed than those obtained with IVUS.[63] Clinically, the detection of thin fibrous caps (vulnerable atheromas) (<65 microns) is below the resolution of the current 40-MHz IVUS (100–200 microns).[60] A summary of testing modalities used in cardiovascular medicine is provided in Appendices 17–1 and 17–2.

CHAPTER 18

Cardiac Arrest

JEFFREY F. BARLETTA AND JEFFREY L. WILT

KEY CONCEPTS

1. High-quality cardiopulmonary resuscitation with minimal interruptions in chest compressions should be emphasized in all patients following cardiac arrest.
2. Chest compressions prior to defibrillation [consistent with the cardiocerebral resuscitation (CCR) model] may lead to more successful outcomes especially with arrests that are not witnessed.
3. The purpose of using vasopressor therapy following cardiac arrest is to augment low coronary and cerebral perfusion pressures encountered during cardiopulmonary resuscitation (CPR).
4. Despite several theoretical advantages with vasopressin, clinical trials have not consistently demonstrated superior results over that achieved with epinephrine
5. Amiodarone remains the preferred antiarrhythmic during cardiac arrest according to the 2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care (or 2005 AHA guidelines) with lidocaine considered as an alternative.
6. Successful treatment of both pulseless electrical activity (PEA) and asystole depends almost entirely on diagnosis of the underlying cause.
7. Intraosseous administration is the preferred alternative route for administration if IV access can not be achieved.

Cardiac arrest is defined as the cessation of cardiac mechanical activity as confirmed by the absence of signs of circulation (e.g., a detectable pulse, unresponsiveness, and apnea).[1] While there is wide variation in the reported incidence of cardiac arrest, it is estimated that there are 294,851 emergency medical services (EMS)-treated out-of-hospital cardiac arrests annually in the United States.[2] Unfortunately, outcomes remain alarmingly poor with survival to hospital discharge ranging from 1.1% to 8.1% in patients who suffer out-of-hospital cardiac arrest.[3] In-hospital cardiac arrest, on the other hand, yields a survival of approximately 20%.[1]

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

EPIDEMIOLOGY

In adult patients, cardiac arrest usually results from the development of an arrhythmia.[4] Historically, ventricular fibrillation (VF) and pulseless ventricular tachycardia (PVT) have been the most common initial rhythm; however, this has changed markedly over time. In one study of out-of-hospital arrests, VF was the first identified rhythm in 61% of patients in 1980 compared to 41% of patients in 2000, a reduction of greater than 30%.[5] More recently, a second study identified VF/PVT as the first recorded rhythm in only 13% of patients.[3] The declining incidence of VF could potentially be due to its association with ischemia and other cardiac causes of arrest (vs noncardiac causes) and the improvements made in the treatment of coronary artery disease.[4,5]

In contrast to out-of-hospital cardiac arrest, VF is the initial rhythm in roughly 20% to 35% of in-hospital cardiac arrests.[1] As in-hospital cardiac arrest is typically preceded by hypoxia or hypotension, asystole, or pulseless electrical activity (PEA) occur more commonly. In fact, one study noticed an incidence of asystole and PEA of 35% and 32%, respectively, while the incidence of VF or PVT was only 23%.[6]

This declining incidence of VF or PVT is somewhat concerning as survival rates are substantially higher compared to asystole or PEA. Hospital survival for in-hospital cardiac arrest related to VF or PVT is approximately 36% (vs 11% with asystole/PEA) with most patients having a good neurologic outcome.[6] Survival for out-of-hospital cardiac arrest due to VF or PVT is approximately 25% to 40%, with higher survival rates being observed in communities that have an organized rapid response system.[3]

In contrast to adult patients, only 14% of pediatric patients with in-hospital arrest present with VF or PVT as the initial rhythm of which 29% survive to hospital discharge.[6] This is probably because most pediatric arrests are respiratory-related as opposed to the primary cardiac etiology seen in adult patients. Unfortunately, survival following pediatric out-of-hospital cardiopulmonary arrest is roughly 7% with most survivors having a poor neurologic status.[2]

ETIOLOGY

Coronary artery disease is the most common clinical finding in adult patients who suffer cardiac arrest and is the etiologic cause for roughly 80% of sudden cardiac deaths.[4] Approximately 10% to 15% of sudden cardiac deaths occur in patients with cardiomyopathies (e.g., hypertrophic cardiomyopathy, dilated cardiomyopathy), while the remaining 5% to 10% are composed of either structurally abnormal congenital cardiac conditions or patients with structurally normal but electrically abnormal heart. Unfortunately, in at least 67% of patients, cardiac arrest is the first clinical sign of coronary artery disease with no preceding signs or symptoms.[7]

In pediatric patients, cardiac arrest is often the terminal event of respiratory failure or progressive shock.[8] Out-of-hospital arrests frequently are associated with events such as trauma, sudden infant death syndrome, drowning, poisoning, choking, severe asthma, and pneumonia, while in-hospital arrests are associated with sepsis, respiratory failure, drug toxicity, metabolic disorders, and arrhythmias.

PATHOPHYSIOLOGY OF CARDIAC ARREST

There are two distinctly different pathophysiologic conditions associated with cardiac arrest. The first is primary cardiac arrest whereby arterial blood is typically fully oxygenated at the time of arrest. The second is cardiac arrest secondary to respiratory failure in which lack of ventilation leads to severe hypoxemia, hypotension, and secondary cardiac arrest. It is important to understand specific condition at hand as different treatment approaches are likely necessary.[9]

TREATMENT

Cardiopulmonary resuscitation (CPR) is an attempt to restore spontaneous circulation by performing chest compressions (to restore threshold blood flows, particularly to the heart and brain) with or without ventilations. There are two proposed theories describing the mechanism of blood flow during CPR.[10] The original theory is known as the cardiac pump theory and is based on the active compression of the heart between the sternum and vertebrae thereby creating forward flow. Echocardiography, however, has revealed that left ventricular size does not always change with compressions and the mitral valve may in fact be open.[10] The second, more recent theory is the thoracic pump theory. This theory is based on intrathoracic pressure alterations induced by chest compressions and the differential compressibility of the arteries and veins. In this model, the heart merely acts as a passive conduit for flow.

The concept of cough CPR supports the importance of changes in intrathoracic pressure as a means of generating forward blood.[11] During vigorous coughing, intrathoracic pressures increase secondary to contractions of the diaphragm, abdominal muscles, and intercostal muscles. These pressure changes occur without direct chest compression and are sufficient to maintain consciousness. The observation that coughing alone can maintain consciousness led many investigators to question the cardiac pump theory and accept the thoracic pump theory. It is likely that both models contribute to the mechanism of blood flow with CPR.

High-quality CPR as suggested in the 2005 AHA guidelines has continued to be evaluated. In one animal model, high-quality compressions compared to standard compressions led to an increase in restoration of spontaneous circulation and neurologically normal survival.[12] In addition, the use of an impedance threshold device, which harnesses the recoil energy of the chest wall decompression (thereby improving cardiac filling) seems to be of benefit and is under continued investigation.[13]

DESIRED OUTCOME

The goal of CPR is the return of spontaneous circulation (ROSC), with effective perfusion (and similarly, ventilation) as quickly as possible to minimize hypoxic damage to vital organs. It is not sufficient to restore spontaneous circulation if the patient is left neurologically devastated or incurs severe morbidity in the process. Factors proved to enhance survival to hospital discharge include the occurrence of a witnessed arrest, rapid implementation of bystander CPR, presence of VF as the initial rhythm, and early defibrillation therapy for VF.[14] In fact, survival rates from witnessed cardiac arrest due to VF/PVT decrease by approximately 7% for every minute between collapse and defibrillation if no CPR is provided. If bystander CPR is provided, however, the decrease in survival is 3% to 4% per minute.[8] Investigators are now evaluating predictors of outcome depending on type of arrest, time to ROSC, and are even validating new tools to evaluate functional outcome after cardiac arrest.[15,16]

GENERAL APPROACH TO TREATMENT

Cardiopulmonary Resuscitation

National conferences and organized committees have played a major role in encouraging widespread competency in CPR technique. The most recent conference was held in 2005 which provides the latest set of recommendations for CPR and emergency cardiovascular care (ECC) (Table 18–1).[8] These guidelines continue to emphasize the "chain of survival" to highlight the treatment approach and illustrate the importance of a timely response.[8] The four links of the chain of survival are

1. Early recognition of the emergency and activation of EMS
2. Early bystander basic life support (BLS) and CPR
3. Early delivery of a shock with a defibrillator
4. Early advanced cardiac life support (ACLS) followed by postresuscitation care delivered by healthcare professionals

While all four links of the chain of survival are important, the most crucial may be the first three, particularly early CPR.[8] CRP provides critical blood flow to the heart and brain, prolongs the time VF is present (prior to the deterioration to asystole) and increases the likelihood that a shock will terminate VF resulting in a rhythm compatible with life.[8] In one study of out-of-hospital cardiac arrest, early recognition of cardiac arrest [odds ratio (OR) 4.4 {95% confidence interval (CI), 3.1-6.4}], early CPR [OR 3.7 (95% CI, 2.5-5.4)], and defibrillation within 8 minutes [OR 3.4 (95% CI, 1.4-8.4] were associated with an increase in survival to hospital discharge.[14] ACLS, on the other hand, did not improve survival [OR 1.1 (95% CI, 0.8-1.5)]. 1 The 2005 AHA guidelines for CPR and ECC, therefore emphasize the provision of high-quality CPR with minimal interruptions in chest compressions.[8]

The use of drug therapy as part of ACLS has devolved to a minimal role since survival to hospital discharge does not appear to be impacted.

Basic Life Support Based on the 2005 AHA guidelines, the initial algorithm is BLS, and the first action is to determine responsiveness of the patient. If there is no response, the rescuer should immediately activate the emergency medical response team, and obtain an automated external defibrillator (AED) if one is available. Next, the victim's airway should be opened, with an assessment of effective breathing. If the victim is not breathing, then two rescue breaths should be administered. Subsequent to this, the rescuer should determine if there is an effective pulse. If there is an effective pulse, then rescue breathing with frequent assessments of effective circulation should be continued until help arrives. If there is no pulse, then chest compressions need to be immediately instituted. The recommended rate is 100 beats/minute, with cycles of 30 compressions followed by 2 rescue breaths. The 2005 AHA guidelines for CPR and ECC stress that there should be minimal interruptions in chest compressions. If there is no AED available, then cycles of compressions/breaths should continue, with pulse checks every 2 minutes (5 cycles) until help arrives or the patient regains spontaneous circulation. If there is an AED available, then the rhythm should be checked to determine if defibrillation is advised. If so, then one shock should be delivered with the immediate resumption

TABLE 18-1 Evidence-Based Treatment Recommendations

Recommendations	Recommendation Grades[b]
Immediate bystander CPR[a] High-quality CPR should be performed with minimal interruption in chest compressions and defibrillation as soon as it can be accomplished.	**Class I**
Epinephrine One milligram IV/IO should be administered every 3 to 5 minutes in patients with VF, PVT, PEA, or asystole	**Class IIb**
Vasopressin Forty units IV/IO may replace either the first or second dose of epinephrine in patients with VF, PVT, or asystole. There is insufficient evidence to recommend either for or against its use in PEA.	**Class Indeterminate**
Amiodarone Three hundred milligrams IV/IO can be followed by 150 mg IV/IO in patients with VF/PVT unresponsive to CPR, shock, and a vasopressor.	**Class IIb**
Lidocaine Lidocaine can be considered an alternative to amiodarone in patients with VF/PVT. The initial dose is 1 to 1.5 mg/kg IV. Additional doses of 0.5 to 0.75 mg/kg can be administered at 5- to 10-minute intervals to a maximum dose of 3 mg/kg if VF/PVT persists.	**Class Indeterminate**
Magnesium Magnesium is recommended for VF/PVT that is caused by torsades de pointes. One to 2 g diluted in 10 mL D5W should be administered IV/IO push over 5 to 20 minutes. Clinical studies have not demonstrated a benefit when magnesium was routinely administered during CPR when torsades de pointes was not present.	**Class IIa**
Fibrinolysis Thrombolytics should be considered on a case-by-case basis when pulmonary embolism is suspected.	**Class IIa**
Hypothermia Hypothermia should be implemented in unconscious adult patients with ROSC after out-of-hospital cardiac arrest when the initial rhythm was VF. These patients should be cooled to 32°C to 34°C for 12 to 24 hours.	**Class IIa**
Hypothermia may be beneficial for patients with non-VF arrest out of hospital or for in-hospital cardiac arrest.	**Class IIb**
Atropine Atropine 1 mg IV/IO every 3 to 5 minutes (maximum total of 3 doses or 3 mg) can be considered for patients with asystole or PEA.	**Class Indeterminate**

[a] CPR, cardiopulmonary resuscitation; IV, intravenous; IO, intraosseous, VF, ventricular fibrillation; PVT, pulseless ventricular tachycardia; PEA, pulseless electrical activity; D5W, dextrose 5% in water.

[b] Key for evidence-based classifications:[8]

Class I: High-level prospective studies support the action or therapy, and the benefit substantially outweighs the potential for harm. The treatment should be administered.

Class IIa: The weight of evidence supports the action or therapy, and the therapy is considered acceptable and useful. It is reasonable to administer the treatment.

Class IIb: The evidence documented only short-term benefits, or positive results were documented with lower levels of evidence. Class IIb recommendations can be considered either optional or recommended by experts despite the absence of high-level supporting evidence.

Class III: The risk outweighs the benefit for a particular treatment. The treatment should not be administered and may be harmful.

Class Indeterminate: This is either a continuing area of research or an area where research is just getting started. No recommendation (either for or against) can be made.

of chest compressions and rescue breaths. After 5 cycles, the rhythm should be reevaluated to determine the need for defibrillation. This algorithm should be repeated until help arrives, or the rhythm is no longer "shockable." If the rhythm is not shockable, then chest compressions—rescue breath cycles should be continued until help arrives, or the victim recovers spontaneous circulation. (Fig. 18–1)

Despite widespread dissemination of cardiac arrest guidelines, and the ongoing education even of health care providers, there is ample evidence that chest compression quality remains poor in general. This has led to further educational interventions in an attempt to increase quality of CPR. In one study, the combination of debriefing and feedback improved the effectiveness of chest compressions from 29% to 64%.[17]

Advanced Cardiac Life Support Once ACLS providers arrive, then further definitive therapy is given. If the rhythm is not shockable, then it is likely to be either asystole or PEA. (Fig. 18–2) The general management of these rhythms is CPR and pharmacologic therapy as listed below. For PEA, the rescuer must consider reversible causes. (Table 18–2) If the person is in VF or PVT, then one shock should be delivered (appropriate to the available electrical device), with the immediate resumption of 30 compressions and 2 breaths for 5 cycles prior to rechecking the rhythm or pulse. If there is still a shockable rhythm, then one shock should be delivered, and at this time pharmacologic intervention can be considered. After the first unsuccessful shock, vasopressors are the initially recommended pharmacologic intervention (before or after the second shock), and after the second unsuccessful shock, antiarrhythmics can be considered (before or after the third shock). Five cycles of chest compressions—breaths should be performed in between attempts at defibrillation. This algorithm will repeat until either a pulse is obtained with effective circulation, the rhythm changes, or the patient expires. For completeness, please refer to the guidelines published by the AHA.[8]

Cardiocerebral Resuscitation

The appropriateness of the 2005 AHA guidelines for ECC has recently been questioned in favor of a concept known as cardiocerebral resuscitation (CCR).[9] This "clarion call for change" was made in light of the suboptimal outcomes observed with the ECC guidelines as well as several limitations with the guideline process.[18] CCR is composed of three major components: (1) continuous chest compressions for bystander resuscitation, (2) a new ACLS algorithm for EMS, and (3) aggressive postresuscitation care including therapeutic hypothermia and early catheterization/intervention.

CCR advocates continuous chest compressions without mouth-to-mouth ventilations for witnessed cardiac arrests. Chest compressions deliver a small but critical amount of oxygen to the brain and myocardium. Cerebral and coronary perfusion pressures, however, build up slowly once chest compressions are begun. These perfusion pressures are lost if chest compressions are stopped to deliver mouth-to-mouth ventilation. In fact, approximately 16 seconds are required to deliver 2 breaths as recommended by the ECC guidelines.[19] The loss of perfusion during this time period is extremely detrimental as ROSC is closely related to perfusion pressures generated during chest compressions.[20] Several clinical trials have documented the benefit of continuous chest compressions (without ventilation) compared to conventional CPR.[21]

The second component of CCR is a new ACLS protocol for EMS. This protocol is based on the 3-phase time-sensitive model of cardiac arrest.[22] The first phase is the electrical phase (0 to 5 minutes), where prompt defibrillation is the most important intervention. The second phase is the hemodynamic phase (5 to 15 minutes), where adequate coronary and cerebral perfusion pressures, before and after defibrillation, are crucial. In fact, defibrillation prior to CPR in this phase commonly leads asystole or PEA. This is likely due to the presence of global tissue ischemia and the need for blood flow (via chest compressions) to "flush out" deleterious metabolic factors that have accumulated during ischemia. The third phase is the metabolic phase (beyond 15 minutes) in which survival is very low and hypothermia may be the most beneficial approach.

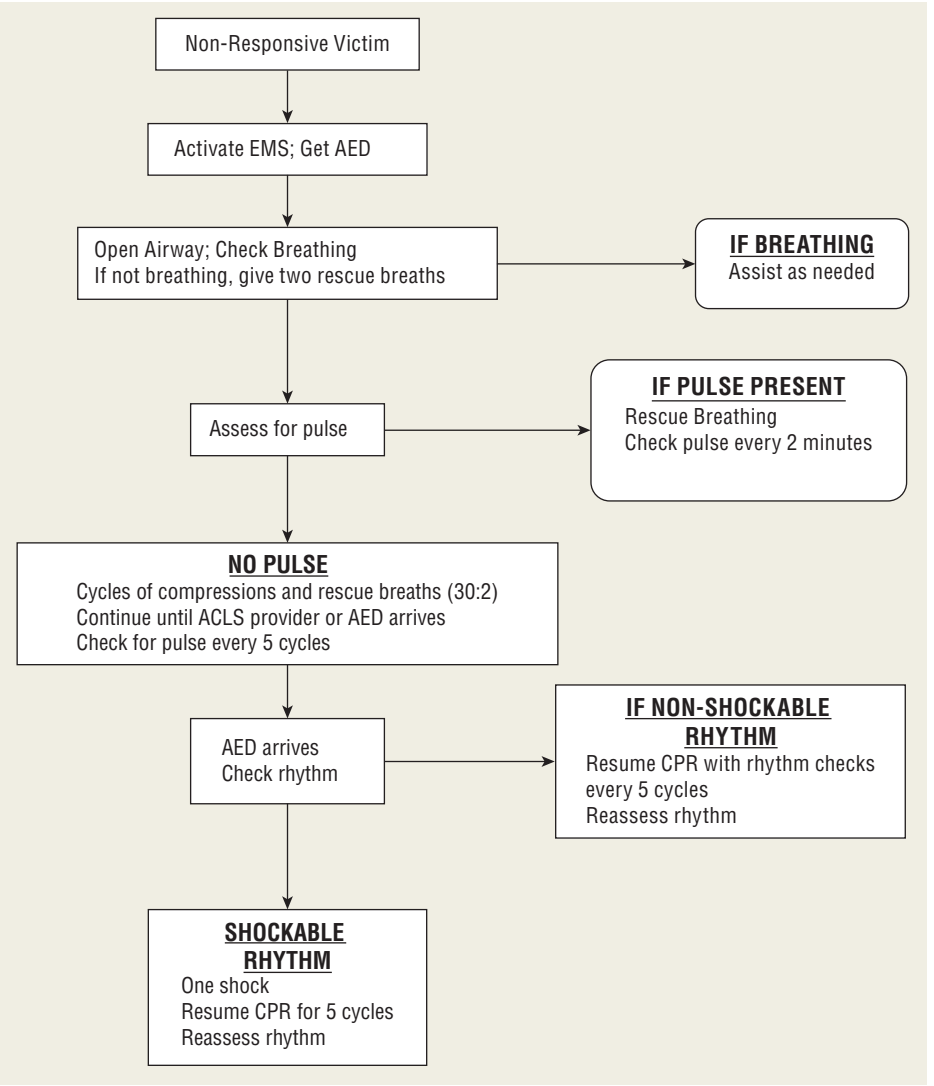

FIGURE 18-1. Treatment algorithm for adult cardiopulmonary arrest: basic life support (BLS)

The third component of CCR is aggressive postresuscitation care. This consists of the use of hypothermia for all comatose patients and emergent cardiac catheterization and percutaneous coronary intervention for patients with myocardial ischemia as a potential cause of their arrest. This and other differences between CCR and CPR are highlighted in Table 18–3. Since its conception in 2003, clinical studies evaluating CCR have demonstrated an improvement in survival of 250% to 300% compared to conventional CPR.[9]

VENTRICULAR FIBRILLATION AND VENTRICULAR TACHYCARDIA

Nonpharmacologic Therapy

Electrical defibrillation is the only effective method of restoring a perfusing cardiac rhythm in either VF or PVT; therefore, it is a crucial link in the "chain of survival," especially for a witnessed arrest.[8] The probability of successful defibrillation is directly related to the time interval between the onset of VF and the delivery of the first shock.[8] In one study, a 23% relative improvement in survival was observed with each 1 minute reduction in the time to defibrillation [OR 0.77 (95% CI, 0.73-0.81)].[23]

2 Although early defibrillation is crucial for survival following cardiac arrest, several studies have suggested that CPR prior to defibrillation (consistent with the CCR model) may lead to more successful outcomes.[24–27]

In one trial, the provision of roughly 90 seconds of CPR prior to defibrillation was associated with an increased rate of hospital survival (compared with a historical control group) when response intervals were 4 minutes or longer (27% vs 17%; $P = 0.01$).[24] A second trial reported higher survival rates in patients with response intervals greater than 5 minutes when 3 minutes of CPR was administered prior to defibrillation (22% vs 4%; $P = 0.006$).[27] In a study where each defibrillation, including the first, was preceded by 200 uninterrupted chest compressions, an increase in total survival [57% (19/33) vs 20% (18/92), $P = 0.001$] and neurologically normal survival [48% (16/33) vs 15% (14/92), $P = 0.001$] was reported compared to standard CPR practices.[26] Finally, one study noted an improvement in hospital survival (from 22% to 44%, $P = 0.0024$) in patients with witnessed VF using a modified resuscitation protocol which included 200 pre-shock chest compressions.[25] In lieu of these results, the 2005 AHA guidelines offer that EMS personnel may give two minutes of chest compressions prior to attempting defibrillation. Recommendations are similar for victims in the metabolic phase recognizing the likelihood of achieving ROSC, however, is drastically lower.

As opposed to the previous guidelines, where "stacked," multiple shocks were initially given, persons in VF or PVT should receive electrical defibrillation with one shock.[8] This revision is largely due to the prolonged time noted (approximately 55 seconds) to deliver three stacked shocks without providing adequate chest compressions.[28] The defibrillation attempt should be with

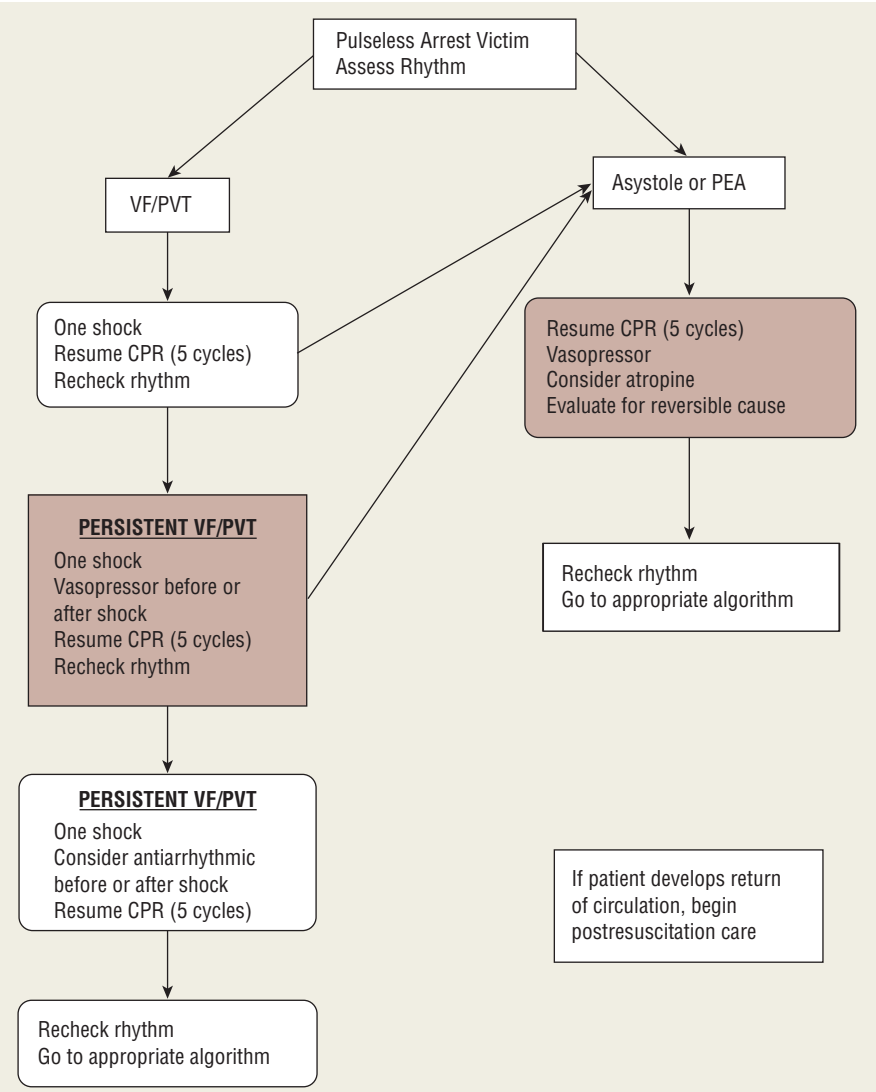

FIGURE 18-2. Treatment algorithm for adult cardiopulmonary arrest: advanced cardiac life support (ACLS)

TABLE 18-2 Potentially Reversible Causes of PEA and Asystole (Think: 6 H's; 6 T's)

Condition	Clues	Treatment
Hypovolemia	History, flat neck veins	Intravenous fluids
Hypoxia	Cyanosis, blood gases, airway problems	Ventilation, oxygen
Hydrogen ion (acidosis)	History of bicarbonate-responsive preexisting acidosis	Sodium bicarbonate, hyperventilation
Hyper (Hypo) kalemia	History of renal failure, diabetes, recent dialysis, dialysis fistulas, medications	Calcium chloride, insulin, glucose, sodium bicarbonate, sodium polystyrene sulfonate, dialysis
Hypothermia	History of exposure to cold, central body temperature	Rewarming, oxygen, intravenous fluids
Hypoglycemia	History of diabetes	Glucose infusion
Toxin (Drug overdose)	Bradycardia, history of ingestion, empty bottles at the scene, pupils, neurologic exam	Drug screens, intubation, lavage, activated charcoal
Tamponade (Cardiac)	History (trauma, renal failure, thoracic malignancy), no pulse with CPR, vein distention, impending tamponade-tachycardia, hypotension, low pulse pressure changing to sudden bradycardia as terminal event	Pericardiocentesis
Tension pneumothorax	History (asthma, ventilator, chronic obstructive pulmonary disease, trauma), no pulse with CPR, neck vein distention, tracheal deviation	Needle decompression
Thrombosis, coronary	History, ECG, enzymes	PCI, thrombolytics, oxygen, nitroglycerin, heparin, aspirin, morphine
Thrombosis, pulmonary	History, no pulse with CPR, distended neck veins	Pulmonary arteriogram, surgical embolectomy, thrombolytics
Trauma	History, examination	Volume infusion, intracranial pressure monitoring, bleeding control, surgical intervention

TABLE 18-3 Cardiocerebral Resuscitation Versus Cardiopulmonary Resuscitation

Cardiocerebral Resuscitation	Cardiopulmonary Resuscitation
Continuous chest compressions for bystanders	Bystander "hands-on" only CPR
Decrease rescue breathing	Decrease interruptions in chest compressions
BLS: No rescue breathing	BLS: 30:2 ratio of chest compressions to ventilations
ACLS: Passive oxygen insufflation or limited breaths per minute	ACLS: 8 to 10 breaths per minute
Two hundred chest compressions prior to shock	Optional 5 cycles of 30:2 prior to shock
Single shock	Single shock
Two hundred chest compressions immediately after shock	Five cycles of 30:2 immediately after shock
Therapeutic hypothermia for all unconscious patients postresuscitation	Therapeutic hypothermia for all unconscious patients postresuscitation from VF cardiac arrest
Early emergent catheterization and PCI for all resuscitated victims regardless of EKG findings	No official statement

360 J (monophasic defibrillator) or 150 to 200 J (biphasic defibrillator). If an AED is available, it should be used as soon as possible. However, CPR should be started immediately (after EMS activation), as the AED is being prepared. If early CPR is provided to a witnessed VF arrest, and defibrillation is able to be provided within 3 to 5 minutes, survival rates have been reported to be has high as 74%.[8,29] Interestingly, AEDs, which have been shown to improve survival in out-of-hospital cardiac arrest due to VF/VT, have not been shown to improve outcome following replacement of monophasic defibrillators with biphasic AEDs for in-hospital arrest.[30]

After defibrillation is attempted, CPR should be immediately restarted and continued for 2 minutes without checking a pulse. The omission of the pulse check after defibrillation is a paradigm shift in the algorithm that is related to myocardial stunning with resultant poor perfusion and diminished cardiac output immediately after electrical therapy.[8] After 2 minutes of chest compressions, the rhythm and pulse should be rechecked. If there is still evidence of VF or PVT, then pharmacologic therapy with repeat attempts at single-discharge defibrillation should be attempted.

Endotracheal intubation and intravenous (IV) access should be obtained when feasible, but not at the expense of stopping chest compressions. The 2005 AHA guidelines for CPR and ECC strongly stress the need for uninterrupted CPR.[8] Once an airway is achieved, patients should be ventilated with 100% oxygen. The recent guidelines suggest that lower tidal volumes and rates may be beneficial.[8] There are several airway adjuncts that are potentially available, such as laryngeal mask airways and esophageal-tracheal combination tubes. However, the definitive airway is an endotracheal tube placed with direct laryngoscopy.

Other interventions are also being evaluated as non-pharmacologic therapy. In a porcine model of VF arrest, a percutaneously placed left ventricular assist device (LVAD) was shown to sustain vital organ perfusion.[31] As well, the performance of angiography and percutaneous coronary intervention during suspected myocardial infarction has been studied in both animals and anecdotally in humans refractory to traditional ACLS protocol without ROSC. A review of this topic suggests that this intervention is feasible and that further investigation is warranted.[32] Extracorporeal membrane oxygenation (ECMO) has also been evaluated and has been shown to improve outcomes in some series, but the logistics of widespread implementation is daunting.[33] While there are no conclusive human data regarding these issues, it does raise interesting concepts to deliberate and research.

Pharmacologic Therapy

Sympathomimetics The use of sympathomimetics is a major part of drug therapy in CPR. ❸ The primary goal of sympathomimetic therapy is to augment low coronary and cerebral perfusion pressures encountered during CPR.

While chest compressions can provide some degree of blood flow to the brain and heart, it is only about 25% of that generally encountered under basal conditions.[34] Animal studies have demonstrated that coronary perfusion pressures above 30 mm Hg are associated with improved survival.[35] In humans, even with properly performed chest compressions, coronary perfusion pressures are only 10 to 15 mmHg, the systolic arterial pressure is rarely above 80 mmHg, the diastolic pressure is low, and the carotid mean pressure is rarely above 40 mm Hg.[8,36]

Epinephrine continues to be a drug of first choice for the treatment of VF, PVT, asystole, and PEA despite a paucity of evidence demonstrating improved survival in humans.[8] (Table 18–4) Epinephrine is both an α- and β-receptor agonist, although its effectiveness is primarily through it's α effects. The β effects may in fact be harmful as β-stimulation increases myocardial oxygen demand and can increase the severity of postresuscitation myocardial dysfunction.[37] This has led some investigators to evaluate simultaneous β-blocker administration in conjunction with sympathomimetic therapy using an animal model.[35,38] Unfortunately, these studies have produced mixed results.

Several studies have compared the effects of pure α_1-agonists, such as phenylephrine and methoxamine, with epinephrine since these agents lack any β-activity.[39,40] These studies have shown the use of α_1-agonists to have no long-term survival advantage over epinephrine. One reason that selective α_1-agonists are not superior to epinephrine is related to the α_2 effects. Agents that have potent α_2 effects (e.g., epinephrine and norepinephrine) may be more effective because the α_2-adrenergic receptors lie extrajunctionally in the intima of the blood vessels, making them more accessible to circulating catecholamines—even in low-flow states that occur during CPR.[40] Furthermore, during ischemia, the number of postsynaptic α_1-receptors decreases, which suggests a greater role for α_2-agonist activity during CPR.[41]

Several investigators have compared norepinephrine with epinephrine.[36,42,43] Norepinephrine is a potent α-agonist (both α_1 and α_2) but also has β_1-agonist effects. In the only large-scale randomized, double-blind, prospective trial that compared norepinephrine with epinephrine in the prehospital cardiac arrest setting, there were no significant differences in ROSC, hospital admission or discharge.[42] A second, smaller study demonstrated higher resuscitation rates with norepinephrine compared to epinephrine (64% vs 32%) but no significant difference in hospital discharge.[43] Consequently, epinephrine remains the first-line sympathomimetic for CPR.

The recommended dose for epinephrine is 1 mg administered by IV or intraosseous (IO) injection every 3 to 5 minutes.[8] This epinephrine dose was derived from animal studies (0.1 mg/kg in a 10 kg dog) and equates to approximately 0.015 mg/kg for a 70 kg human.[44] Both animal and human studies have demonstrated a positive dose—response relationship with epinephrine suggesting that higher doses might be necessary to improve hemodynamics and

achieve successful resuscitation.[45,46] These results, however, have not been replicated in human studies[42,47-54] (Table 18–4). Collectively, these studies have shown that high-dose epinephrine may increase the initial resuscitation success rate but that overall survival is not significantly different. The discrepancy between animal and human studies may be due to the fact that most victims of cardiac arrest have coronary artery disease, a condition not present in an animal model. In a human model, however, atherosclerotic plaques can aggravate the balance between myocardial oxygen supply and demand. Moreover, the interval from arrest to treatment in animal studies is shorter than the interval frequently reported in human studies. Since time to CPR and defibrillation are crucial variables for success, prolonging this time period can lower resuscitation rates.

Vasopressin Vasopressin, also known as *antidiuretic hormone*, is a potent, nonadrenergic vasoconstrictor that increases blood pressure and systemic vascular resistance. Although it acts on various receptors throughout the body, its vasoconstrictive properties are due primarily to its effects on the V_1 receptor.[55] Measurement of vasopressin levels in patients undergoing CPR has shown a high correlation between the levels of endogenous vasopressin released and the potential for ROSC.[55] In fact, in one study, plasma vasopressin concentrations were approximately three times as high in survivors compared with nonsurvivors, suggesting that vasopressin is released as an adjunct vasopressor to epinephrine in life-threatening events such as cardiac arrest.[56]

Vasopressin may have several advantages over epinephrine. First, the metabolic acidosis that frequently accompanies cardiac arrest can blunt the vasoconstrictive effect of adrenergic agents such as epinephrine. This effect does not occur with vasopressin. Second, the stimulation of β-receptors caused by epinephrine can increase myocardial oxygen demand and complicate the postresuscitative phase of CPR. Because vasopressin does not act on β-receptors, this effect does not occur with its use. Vasopressin also may have a beneficial effect on renal blood flow by stimulating V_2-receptors in the kidney, causing vasodilation and increased water reabsorption. With regard to splanchnic blood flow, however, vasopressin has a detrimental effect when compared to epinephrine.[57]

4 Despite several theoretical advantages with vasopressin, clinical trials have not consistently demonstrated superior results over that achieved with epinephrine. (Table 18–5) In one large trial of out-of-hospital arrest, no significant differences were noted in ROSC, hospital admission rate or discharge rate.[58] Although, when patients were stratified according to their initial rhythm, patients with asystole, had a significantly higher rate of hospital admission (29% vs 20%; $P = 0.02$) and discharge (4.7% vs 1.5%; $P = 0.04$) with vasopressin compared to epinephrine. In addition, a subgroup analysis of 732 patients who required additional epinephrine therapy despite the two doses of study drug revealed significant benefits in ROSC (37% vs 26%; $P = 0.002$), hospital admission rate (26% vs 16%; $P = 0.002$), and discharge rate (6.2% vs 1.7%; $P = 0.002$) with vasopressin. There was a trend, however, toward a poorer neurologic state or coma among the patients who survived to discharge and received vasopressin.

The favorable results from the subgroup analysis led to a prospective study evaluating the combination of vasopressin and

epinephrine versus epinephrine alone.[59] In this study, patients were randomized to receive either 1 mg of epinephrine followed by 40 units of vasopressin (in less than 10 seconds) or 1 mg of epinephrine plus saline placebo. Unfortunately, there were no significant differences between the combination therapy group and epinephrine only group in any of the outcome measures studied (ROSC, survival to hospital admission, survival to hospital discharge, 1 year survival and good neurologic recovery at discharge). In contrast, a post-hoc subgroup analysis revealed a lower rate of survival (0% vs 5.8%, $P = 0.02$) with combination therapy when the initial rhythm was PEA.

A second study evaluated combination therapy for in-hospital cardiac arrest.[60] In this study, patients were randomized to receive either epinephrine alone or 20 units of vasopressin plus 1 mg of epinephrine and 40 mg of methylprednisolone (followed by hydrocortisone in the post-resuscitative phase). Vasopressin 20 units plus epinephrine 1 mg were repeated during each of 4 subsequent CPR cycles. This study marks the first to include corticosteroids as part of drug-therapy during CPR. The rationale is based on the hemodynamic effects of steroids alone with their potential to impact the intensity of the postresuscitation systemic inflammatory response and organ dysfunction. Significant benefits were observed in ROSC (81% vs 52%, $P = 0.003$) and survival to hospital discharge (19% vs 4%, $P = 0.02$) with combination therapy including corticosteroids. Future studies are required to determine the role of vasopressin and corticosteroids for cardiac arrest.

Antiarrhythmics The purpose of antiarrhythmic drug therapy following unsuccessful defibrillation and vasopressor administration is to prevent the development or recurrence of VF and PVT

by raising the fibrillation threshold. Clinical evidence demonstrating improved survival to hospital discharge however is lacking. As the role of antiarrhythmics during CPR remains limited, only two individual agents are currently recommended in the 2005 AHA guidelines for CPR and ECC: amiodarone and lidocaine.

The use of lidocaine has been beneficial in animal studies and in patients with arrhythmias following an acute myocardial infarction but its benefit in cardiac arrest remains questionable. In the only published case-control trial where patients were classified according to whether they received lidocaine, no significant difference was noted in ROSC, admission to the hospital, or survival to hospital discharge between groups.[61] Similarly, a prospective study comparing the effectiveness of lidocaine with that of standard-dose epinephrine showed not only a lack of benefit with lidocaine but also a higher tendency to promote asystole.[62] In contrast, a retrospective analysis in patients with VF indicated that lidocaine was associated with a higher rate of ROSC and hospitalization ($P<0.01$) but not an increase in the hospital discharge rate.[63]

Amiodarone is classified as a class III antiarrhythmic but possesses electrophysiologic characteristics of all four Vaughn Williams classifications. In a large, randomized, double-blind trial in out-of-hospital cardiac arrest secondary to VF or PVT (also known as the *ALIVE trial*), patients were randomized to receive either amiodarone 300 mg or placebo.[64] Recipients of amiodarone were more likely to be resuscitated and survive to hospital admission than were recipients of placebo (44% and 34%, respectively; $P = .03$). There was no difference in survival to hospital discharge (amiodarone, 13.4% vs placebo, 13.2%; P = NS). This was the first trial to demonstrate the benefit of an antiarrhythmic agent over placebo in patients with out-of-hospital cardiac arrest.

A subsequent trial (known as the *ALIVE trial*) compared amiodarone 5 mg/kg with lidocaine 1.5 mg/kg in patients with out-of-hospital cardiac arrest due to VF.[65] In this trial, amiodarone was associated with a relative improvement of 90% in survival to hospital admission compared with lidocaine [22.8% vs 12%; OR 2.17 (95% CI 1.21-3.83); $P = 0.009$]. Similar to the ARREST trial, there was no difference in survival to hospital discharge (amiodarone, 5% vs lidocaine, 3%; $P = .34$).

Amiodarone and lidocaine have also been compared following in-hospital cardiac arrest secondary to VF or PVT. In a multicentered, retrospective review, 194 patients who received amiodarone ($n = 74$), lidocaine ($n = 79$), or both ($n = 41$) were evaluated.[66] The rate of survival at 24 hours was 55%, 63%, and 50% for patients receiving amiodarone, lidocaine, or both, respectively ($P = 0.39$). There was no difference in survival to hospital discharge (39% for amiodarone, 45% for lidocaine, and 42% for patients receiving both agents; $P = 0.72$). After adjusting for multiple covariates, Cox regression analysis revealed higher mortality for those patients who received amiodarone (as opposed to lidocaine) [survival to 24 hours: hazard ratio was 3.15 (95% CI, 1.68-5.92), $P<0.001$; survival to hospital discharge: hazard ratio was 3.25 (95% CI, 1.22-8.65), $P = 0.02$] and in those patients with VF/PVT as the initial rhythm (as opposed to bradycardia followed by VF/PVT) [survival to 24 hours: hazard ratio was 3.36 (95% CI, 1.98-5.71), $P<0.001$; survival to hospital discharge: hazard ratio was 3.6 (95% CI, 1.2-10.6), $P = 0.021$]. The mean initial dose of amiodarone, though, was 190 mg, and only 25% of patients received the recommended dose of 300 mg. Additionally, the time to first dose of antiarrhythmic was significantly longer in the amiodarone group than in the lidocaine group (14 minutes vs 6 minutes, $P<0.001$). While these differences could have biased the results in favor of lidocaine, they provide a real-world experience with the use of amiodarone. Further large-scale trials are needed to determine the preferred antiarrhythmic for both in-hospital and out-of-hospital cardiac arrest. 5 In the meantime, amiodarone remains the preferred antiarrhythmic during cardiac arrest according to the 2005 AHA guidelines for CPR and ECC with lidocaine considered as an alternative.[8]

Thrombolytics Since most cardiac arrests are related to either MI or PE, several investigators have evaluated the role of thrombolytics during CPR. While these studies have demonstrated successful use of thrombolytics, few have shown improvements to hospital discharge[67-76] (Table 18–6). In the largest published randomized controlled trial to date, tenecteplase was compared with placebo for out-of-hospital cardiac arrest. Unfortunately, enrollment was stopped early due to futility in meeting their primary endpoint, 30 day survival.[74] Survival in the tenecteplase and placebo groups, respectively, was 15% and 17% ($P = 0.36$). Potential reasons for failure in this study include the lack of antiplatelet and antithrombin medications and decreased delivery of the thrombolytic to the coronary arteries (where the clots exist) due to impaired flow and perfusion. Of note, intracranial hemorrhage occurred with significantly greater frequency with tenecteplase versus placebo (2.7% vs 0.4%, $P = 0.006$). The role of thrombolytics as part of CPR will require further study.

Magnesium While severe hypomagnesemia has been associated with VF/PVT, clinical trials have not demonstrated any benefit with the routine administration of magnesium during a cardiac arrest. Two observation trials though have shown an improvement in ROSC in patients with arrests associated with torsades de pointes.[8] Therefore, magnesium administration should be limited to these patients.

Postresuscitative Care

Following the ROSC from a cardiac arrest, a complex phase of resuscitation begins which has been termed post-cardiac arrest syndrome.[77] There are four main components of post-cardiac arrest syndrome which highlight succinct pathophysiologic processes and potential areas for treatment (Table 18–7). They are post-cardiac arrest brain injury, myocardial dysfunction, systemic ischemia/reperfusion response and persistent precipitating pathology.[77] In general, many of the concepts within these 4 components surround the principles of basic ICU care (e.g., early hemodynamic optimization, circulatory support, sedation, etc). For a detailed description, the reader is referred either to the corresponding chapter in this text or to evidence-based consensus statements.[77] One particular area, however that is specific to cardiac arrest is the concept of therapeutic hypothermia.

Restoration of blood flow following cardiac arrest can lead to several chemical cascades and destructive enzymatic reactions that can result in cerebral injury. These reactions include free-radical production, excitatory amino acid release, and calcium shifts, leading to mitochondrial damage and apoptosis (programmed cell death).[78] Hypothermia can protect from cerebral injury by suppressing these chemical reactions, thereby reducing the production of free radicals. Various animal models have demonstrated improved functional recovery and reduced cerebral deficits with the induction of mild therapeutic hypothermia [78,79] Recent data has attempted to refine this concept, and even expand upon the organ systems protected. In a pig model of VF treated after 10 minutes, rapid head cooling led to more beneficial effects than surface cooling in terms of postresuscitation myocardial dysfunction.[80] In addition, a similar pig model of cardiac arrest showed that delayed surface cooling led to less favorable survival and neurologic outcome than early head cooling.[81]

Interestingly, hypothermia as a therapeutic endeavor in humans has been described since antiquity. It is reported that Hippocrates suggested packing bleeding patients in snow and ice for treatment, and also that a chief surgeon of Napoleon Bonaparte's noticed that wounded soldiers who were rewarmed survived less than those who were left in the cold.[82,83]

Data from references (67–76)

These early human observations, as well as current animal model investigations, have been parlayed into the clinical bedside in human trials, and literature continues to accumulate. Early human success with hypothermia was described in two pivotal trials.[84,85]

The first trial was conducted in nine centers in five European countries.[84] In this study, patients who had been resuscitated after cardiac arrest due to VF but remained comatose were assigned randomly to undergo therapeutic hypothermia, targeting a temperature of 32° to 34°C, for 24 hours. The primary end point was neurologic outcome within 6 months of cardiac arrest. Secondary end points were mortality (within 6 months) and complication rate within 7 days. A favorable neurologic outcome was achieved in 55% of patients in the hypothermia group as opposed to 39% in the normothermia group ($P = 0.009$). Additionally, mortality rates were improved significantly in the hypothermia group (41% vs 55%; $P = 0.02$). Based on this difference, seven patients would need to be treated with hypothermia to prevent one death. The rate of complications (e.g., bleeding, pneumonia, sepsis, and renal failure) did not differ between the two groups (73% for the hypothermia group and 70% for the normothermia group; $P = 0.70$).

The second trial was conducted in four hospitals in Melbourne, Australia.[85] Entry criteria were similar to the previous trial, but the target temperature for hypothermia was 33°C, which was maintained for 12 hours. The primary outcome measure was survival to hospital discharge with good neurologic function. Forty-nine percent of patients in the hypothermia group had good neurologic function on discharge (to either home or a rehabilitation facility) compared with 26% of patients in the normothermia group ($P = 0.046$). Mortality rates were similar between the two groups (51% for the hypothermia group and 68% for the normothermia group; $P = 0.145$). Hypothermia was associated with a lower cardiac index, higher systemic vascular resistance, and hyperglycemia. It is important to note that only 8% of patients with cardiac arrest were selected for therapeutic hypothermia in these two studies.

Since that time, further data has continued to accumulate. In one study therapeutic hypothermia (combined with percutaneous coronary intervention, tight glycemic control, and seizure control) doubled the one-year survival rate (reportedly with good brain function) from 26% to 56%.[86] The implementation of therapeutic hypothermia in clinical practice (i.e., outside of the context of a clinical trial) has also been evaluated. A review of this topic showed that there is a significant variation in reported protocols, but that survival and neurological outcomes benefit from post-arrest hypothermia "are robust when compared over a wide range of studies of actual implementation" [OR (95% CI) = 2.5 (1.8-3.3)].[87] Nevertheless, there is significant debate about hypothermia including when to consider limitation of care given predicted poor outcome.[88] Initially hypothermia was described with only VF without sustained circulatory shock. As part of the "cardiocerebral" concept described above, investigators are expanding the use to non VF arrests since similar benefit is being found.[15]

Methods of inducing hypothermia are also in evaluation. There is debate over how quickly to achieve a therapeutic temperature, and in at least one animal model, a novel immersion device showed an average time to reach target temperature of only 9 minutes.[89] As well, simple maneuvers, such as iced saline infusion, can be used even in the pre-hospital setting with subsequent cooling by other

means.[90] This has led to editorials clamoring for ongoing studies regarding methodologies and outcomes.[91,92]

In light of these accumulating data, unconscious adult patients with spontaneous circulation after out-of-hospital cardiac arrest should be cooled to 32°C to 34°C for 12 to 24 hours when the initial rhythm was VF.[8,78,87] Such cooling also may be of benefit for other rhythms or in-hospital cardiac arrests. There is insufficient evidence to make a recommendation on the use of therapeutic hypothermia in children, however an evaluation in neonates with asphyxiation suggested that hypothermia in this select population may be beneficial.[93]

Hypothermia must be used with caution, however, as there are several complications that can develop. Coagulopathy, dysrhythmias, hyperglycemia, increased incidence of pneumonia, as well as sepsis have been described.[85,94] In addition, hypothermia can have profound effects on drug distribution and elimination.[95] Further research is proceeding in this area.

NON-VF/PVT RHYTHMS: PEA AND ASYSTOLE

Nonpharmacologic Therapy

Pulseless electrical activity is defined as the absence of a detectable pulse and the presence of some type of electrical activity other than VF or PVT. Several studies have documented that patients with PEA actually have mechanical cardiac contractions, but they are too weak to produce a palpable pulse or blood pressure. Asystole is defined as the presence of a flat line on the ECG monitor. Although PEA is still classified as a "rhythm of survival," the success rate of treatment is much lower than the rates seen with VF/PVT.[6] PEA is often caused by treatable conditions, and the resuscitation team needs to identify and correct these conditions emergently if the resuscitation is to be successful. The rate of survival among patients with out-of-hospital cardiac arrest secondary to asystole is 1% to 2% but may be up to 10% in patients with in-hospital arrest.[5,6,14] 6 Successful treatment of both PEA and asystole depends almost entirely on diagnosis of the underlying cause (Table 18–2).

The algorithm for treatment of PEA is the same as the treatment of asystole. Both conditions require CPR, airway control, and IV access. Asystole should be reconfirmed by checking a second lead on the cardiac monitor. Defibrillation should be avoided in patients with asystole because the parasympathetic discharge that occurs with defibrillation may reduce the chance of ROSC and worsen the chance of survival. The emphasis in resuscitation is good quality CPR without interruption, and to try to identify a correctable cause. If available, transcutaneous pacing can be attempted. Asystole often represents confirmation of death rather than a rhythm to be treated; therefore, withdrawal of efforts must be strongly considered if there is not a rapid ROSC.[8]

Much like VF/PVT, there is an interest in hypothermia in these post-arrest patients. Metabolic parameters (e.g., lactate and O_2 extraction) have been shown to be improved when post-arrest comatose adults survived their arrest and were treated with hypothermia.[96] Further studies are warranted in this area.

Pharmacologic Therapy

The primary pharmacologic agents used in the treatment of asystole are vasopressors (i.e., epinephrine and vasopressin) and atropine. Studies comparing epinephrine and vasopressin in patients with PEA and asystole have not consistently demonstrated an advantage with one agent over the other. In one large trial of patients with out-of-hospital cardiac arrest, a post-hoc, subgroup analysis was conducted for those patients with asystole.[58] In these patients, survival to hospital admission (29% vs 20%, $P = 0.02$) and discharge (4.7% vs 1.5%, $P = 0.04$) were significantly higher with vasopressin compared to epinephrine. There was, however, a non-statistically significant increase in coma/vegetative state with vasopressin (40% vs 0%, $P = 0.014$). In contrast to these findings, a second study which evaluated combination therapy with vasopressin and epinephrine, did not report an advantage with vasopressin in patients with asystole.[59] In fact, a post-hoc subgroup analysis of patients with PEA as the initial rhythm, revealed a lower rate of survival (0% vs 5.8%, $P = 0.02$) with combination therapy compared to epinephrine alone.

Atropine is an antimuscarinic agent that blocks the depressant effect of acetylcholine on both the sinus and atrioventricular nodes, thus decreasing parasympathetic tone. During asystole, parasympathetic tone may increase because of the vagal stimulation that occurs secondary to intubation, the effects of hypoxia and acidosis, or alterations in the balance of parasympathetic and sympathetic control.[97] Unfortunately, there are no prospective controlled trials showing benefit from atropine for the treatment of asystole or PEA.

Earlier small observational reports found some response to atropine in asystole or pulseless idioventricular rhythm but little evidence to suggest that long-term outcomes were altered.[98] In one retrospective case-control study, a success rate of 14% (6 of 43) was noted with atropine compared with to a 0% (0 of 41) rate with a control but no patients survived to hospital discharge.[98] In a second retrospective study, asystole was terminated in only 4 of 22 patients (18%) when atropine was administered.[99] Once again, none survived to hospital discharge. Finally, a third retrospective review evaluated 101 patients who received atropine for asystole.[100]

Twenty-four patients (24%) survived 24 hours after resuscitation. It is unclear how many survived to hospital discharge. These results show that although atropine may achieve ROSC in some instances, asystolic arrest is almost always fatal. Given the relative safety of atropine, the ease of administration, low cost and theoretical advantages, atropine should be considered for asystole or PEA.[8] The beneficial effects however are limited.

ACID-BASE MANAGEMENT

Acidosis seen during cardiac arrest is the result of decreased blood flow (leading to anaerobic metabolism) or inadequate ventilation. Chest compressions generate only approximately 20% to 30% of normal cardiac output, leading to inadequate organ perfusion, tissue hypoxia, and metabolic acidosis. In addition, the lack of ventilation causes retention of carbon dioxide, leading to respiratory acidosis. This combined acidosis produces not only reduced myocardial contractility and negative inotropic effect, but also the appearance of arrhythmias because of a lower fibrillation threshold. In early cardiac arrest, adequate alveolar ventilation has been considered the mainstay of control to limit the accumulation of carbon dioxide and control the acid-base imbalance.[8] With the evolution to CCR, however, there are experts arguing against ventilation because of the negative effects it can have on the effectiveness of CPR. This has led to evidence showing no negative effects if compression-only CPR is used for out-of-hospital cardiac arrest (exceptions being pediatric arrest, drowning, trauma, airway obstruction, non-cardiac etiology, or due to acute respiratory disease).[101] With arrests of long duration, buffer therapy is often considered, however little data supports its use during cardiac arrest.

Although sodium bicarbonate was once given routinely to reduce the detrimental effects associated with acidosis (e.g., reduced myocardial contractility), enhance the effect of epinephrine, and improve the rate of defibrillation, there are few clinical data supporting its use.[102] In fact, sodium bicarbonate may have some detrimental effects.[102,103] The effect of sodium bicarbonate can be described by the following reaction:

$$[HCO_3^-] + [H^+] \leftrightarrow [H_2CO_3] \leftrightarrow [H_2O] + [CO_2]$$

When sodium bicarbonate is added to an acidic environment, this reaction will shift to the right, thereby increasing tissue and venous hypercarbia. The carbon dioxide generated by this reaction will diffuse into the cell and decrease intracellular pH. The accumulation of intracellular carbon dioxide, specifically within the myocardium, is inversely correlated with coronary perfusion pressure produced by CPR. Intracellular acidosis also will decrease myocardial contractility, further complicating the low-flow state associated with CPR.[102] Furthermore, treatment with sodium bicarbonate often overcorrects extracellular pH because sodium bicarbonate has a greater effect when the pH is closer to normal.[103] The induced alkalosis, causes an increase in the affinity of oxygen to hemoglobin ("left shift"), thus interfering with oxygen release into the tissues. More recently, the early administration of bicarbonate (1 mEq/kg) had no effect on survival in pre-hospital cardiac arrest. There was a slight trend toward improvement in prolonged arrest (>15 mins) with a twofold improvement in survival (32.8% vs 15.4%).[104]

Sodium bicarbonate can be used in special circumstances (i.e., underlying metabolic acidosis, hyperkalemia, salicylate overdose, or tricyclic antidepressant overdose), however the dosage should be guided by laboratory analysis if possible. There has been clinical interest in other buffering agents (Carbicarb, Tham, Tribonat) as they have shown less potential for the adverse effects seen with sodium bicarbonate.[8] However there is a dearth of clinical experience with these agents, and outcome studies are not available.

MODIFICATIONS FOR SPECIAL SITUATIONS

Drowning

Drowning is a process resulting in primary respiratory impairment from immersion in a liquid. It is a common, preventable cause of morbidity and mortality. The most important inciting event is the hypoxia induced by submersion. Thus, early care of the drowning patient includes immediate rescue breathing, even before they are removed from the water. Prompt initiation of this therapy increases chance of survival.[105] Once the victim is removed from the water, immediate chest compressions should be started if they are pulseless. Drowning victims can present with any of the pulseless rhythms; standard guidelines need to be followed for therapy of these rhythms.

Hypothermia

Unintentional hypothermia (as opposed to the therapeutic hypothermia used post-arrest, described above) is defined by a body temperature <30°C (86°F), and is associated with marked derangements in body function. Because it can depress virtually every body system, including pulse and respiration, the patient may appear to be dead upon the initial evaluation. Hypothermia may lead to benefit on brain recovery after cardiac arrest (discussed earlier), thus aggressive intervention is clearly indicated when there is a hypothermic arrest victim.

If the patient still has a perfusing rhythm, therapy is mainly based upon rewarming techniques. For mild hypothermia [i.e., >34°C (>93.2°F)], passive rewarming is recommended. For moderate hypothermia [i.e., 30°C to 34°C (86°F to 93.2°F)], active external rewarming is recommended, and for severe hypothermia [i.e., <30°C (<86°F)] active internal rewarming is recommended. These patients need to be manipulated very gently as VF is sometimes precipitated by movement.[106]

If the patient is in cardiac arrest, then the standard BLS algorithm should be followed. However, there are some modifications that the rescuer needs to consider. The rescuer should evaluate for respiration and pulse for a longer timeframe, since these may be slow or very difficult to realize. If there is no breathing, then rescue breaths should ensue. If there is any doubt about the presence of a pulse, then chest compressions should be started immediately. If the patient is in VF or PVT then electrical therapy should be given in a standard manner. However, the hypothermic heart may be less responsive to medications or defibrillation, and thus there have been worries about the optimal temperature at which to start defibrillation attempts.[8] There are no published consensus guidelines regarding this. Immediately after defibrillation, CPR should resume as in the standard manner. During CPR, continued attempts at rewarming are of paramount importance. Included in this concept is preventing further heat loss (i.e., removal of wet clothing, protection from the environment, etc). Patients often require significant volume challenges during the rewarming process. The use of steroids, antibiotics, and barbiturates has been proposed, but none of these agents have ever been shown to increase survival rates.[8]

It is debatable when to stop resuscitative efforts in the hypothermic patient. Many authors have proposed that a patient should not be pronounced until the core temperature has been restored to near normal.[8] Once the patient is in the hospital, it is still the judgment of the treating physician when efforts should be terminated.

Pregnancy

Pregnancy is a unique situation in that survival of both the fetus and the mother depend on CPR. The best hope for survival of the fetus is maternal survival. Because of the gravid uterus, resuscitation needs to be modified. Since the vena cava and aorta can be obstructed by a uterus of approximately 20 weeks gestation or later, it is appropriate to position the patient approximately 15 to 30 degrees back from the left lateral decubitus position, or to pull the uterus to the side.[107] The optimal angle has been cited to be 27 degrees, and has led to the development of the "Cardiff resuscitation wedge" which has been specifically designed for performing CPR on pregnant patients.[108]

Airway control is important in the pregnant patient. The airway may be smaller because of the hormonal changes and edema which accompany pregnancy.[108] Similarly, because of increased intra-abdominal pressure exerted by the uterus, as well as hormonal changes that change the resting state of the gastroesophageal sphincter, clinicians need to be acutely aware of the increased risk of aspiration. Because of this, cricoid pressure needs to be maintained continuously during airway manipulation. The rescuer may need to give smaller tidal volumes than normal because of the diaphragm elevation that accompanies the later stages of pregnancy. Because of the increased ventilatory needs in pregnancy as well as the anatomic changes, some authors have suggested that it is important to perform early intubation during cardiac arrest in pregnancy and cite this rapid intubation as a difference from non-pregnant patients.[108] Similarly, circulatory support also has to be adjusted. In particular, chest compressions need to be administered slightly above the center of the sternum to adjust for the anatomic changes of the pregnant uterus.[8]

In an arrest situation during pregnancy the ACLS provider needs to follow the standard guidelines, including the same use of defibrillation and medications. While it is true that vasoactive agents, such as epinephrine, can diminish uterine blood flow, safer alternatives do not exist.[8] Available literature, though scant, suggests that the energy requirements for defibrillation do not change in pregnancy.[109]

While etiologies of arrest in pregnancy are often the same as in the non-pregnant patient, there are several unique situations that need to be considered in the differential diagnosis of a pregnancy arrest. These include excess magnesium sulfate institution (i.e., iatrogenic from treating eclampsia) in which case the therapeutic administration of calcium gluconate can be lifesaving; amniotic embolism, which is associated with complete cardiovascular collapse during labor and delivery (cardiopulmonary bypass has been reportedly successful in salvaging this condition); pre-eclampsia/eclampsia developing after the 20th week of gestation producing hypertension and multiple organ dysfunction; as well as vascular events including acute coronary syndromes and acute pulmonary embolism.[108,110,111]

It is paramount to remember that unless circulation is restored to the mother, both the mother and the fetus will succumb, especially if standard therapy is not used correctly and promptly. Because of this the resuscitation leader should consider the need for emergent hysterotomy (i.e., Cesarean delivery) and delivery as soon as the arrest happens. The best survival reported for infants > 24 weeks gestation happens when delivery occurs no more than 5 minutes after the arrest of the mother.[8]

Trauma

Cardiac resuscitation of the trauma arrest patient is basically performed with the same guidelines as any other arrest. There are some specific etiologies to rapidly consider however, since the survival of an out-of-hospital cardiac arrest due to trauma is rare.[8] The rescuer needs to consider airway obstruction, pneumothorax, tracheobronchial injury, cardiac or large arterial injury, cardiac tamponade, severe head injury with secondary cardiac collapse, and other injuries specific to the particular trauma.[8] The best survival seems to be in young patients with treatable penetrating injuries.

Trauma patients often suffer head or cervical injuries; thus cervical spine precautions should be used in these patients. A jaw thrust maneuver is the preferred way to open the airway, with in-line stabilization during attempts at advanced airway placement.[8] The rescuer must be vigilant for the development of tension pneumothorax during ventilation. Inadequate ventilation of one side is usually due to tube malposition, tension pneumothorax, or hemothorax. These conditions are usually treated by medical personnel at the hospital after transport.

Chest compressions should be performed in a standard manner. Any visible hemorrhage should be controlled with direct pressure. Fluid resuscitation is done with a goal of adequate blood pressure and organ perfusion. The specific details of fluid resuscitation are highly controversial however, and the optimal volume infusion for trauma resuscitation is a subject of ongoing debate.

Open thoracotomy for trauma-induced arrest has been performed in many instances. For penetrating chest trauma patients who arrest immediately before arrival or in the emergency department, open thoracotomy can allow relief of tamponade, control of major vessel hemorrhage, or direct repair of cardiac insult.[8] In the case of blunt trauma however, open thoracotomy has not been shown to definitively improve outcome. However, there is some suggesting that a physician-led out-of-hospital thoracotomy for penetrating trauma may have a higher chance of survival.[112]

For definitive post-arrest care, trauma patients should be rapidly transferred to a facility with expertise in the provision of trauma care.

Electrical Shock

There are many etiologies of electrical shock injuries, from lightning strike (mortality estimated to be 30%, with 70% of survivors sustaining significant morbidity) to high-tension current, to household current.[8] The severity of injury depends on the site, type of current, duration of contact, pathway, and the magnitude of delivered electricity.

Cardiac arrest is common in electrical injury due to current passing through the heart during the "vulnerable period" of the cardiac cycle. In large-current events, such as lightning strike, the heart undergoes massive depolarization simultaneously.[113] Sometimes the intrinsic pacemaker can restore an organized cardiac electrical cycle, but because of injury to other muscles, specifically the thoracic musculature, the patient cannot retain or sustain viable circulation due to the lack of ventilation and oxygenation.[114]

When approaching a victim of electrocution, the rescuer must first be certain of his or her own safety. Thereafter, standard BLS, prompt CPR, and ACLS when available is indicated. Electric shock is often associated with multiple trauma, including spinal injury, multiple injuries to the skeletal muscles, as well as fractures. These factors need to be evaluated by the resuscitation team.

Airway control may be difficult due to the edema that often accompanies such injuries; thus an advanced airway early in the treatment process is recommended.[8] With soft tissue swelling, there is often a need for aggressive fluid resuscitation in these patients. The underlying tissue, or visceral organ damage, is often worse than the external appearance. It is usually recommended that these patients be transferred to centers with expertise in dealing with these types of injuries.

GUIDELINES FOR DRUG ADMINISTRATION

The routes of administration that are available for drug delivery during CPR include IV (both central and peripheral access), IO, and endotracheal. The chosen route represents a compromise between

the availability of access and their apparent efficacy in introducing the drug into the central circulation. When selecting a route for drug administration, it is of utmost importance to minimize any interruptions in chest compressions during CPR.

Central venous access will result in a faster and higher peak drug concentration than peripheral access but central line access is not needed in most resuscitation attempts. If a central line is already present, however, it should be the access site of choice. Central lines located above the diaphragm are preferable to those located below the diaphragm because of poor blood flow during CPR.[115] If IV access (either central or peripheral) has not been established a large peripheral venous catheter should be inserted. It has been suggested that only one attempt at peripheral IV insertion be allowed.[116] If this is not successful, an IO device should be inserted. Of note, peripheral drug administration yields a peak concentration in the major systemic arteries in roughly 1.5 to 3 minutes but circulation time can be shortened by up to 40% if the drug is followed by a 20-mL fluid bolus with elevation of the extremity.[115]

7 IO administration is the preferred alternative route for administration if IV access can not be achieved.[8] Drug administration using the IO route is as quick and effective as drug administration via central access and superior to that achieved with peripheral access. Several studies have documented the effectiveness and safety of this administration route in both adults and children.[8] Potential anatomic sites for insertion for an IO needle are the distal tibia, the proximal tibia and the distal femur.[117] IO infusion devices are available that allow for rapid insertion (i.e., within 60 seconds) and are easy to use.[118]

In the event that neither IV nor IO access can be established, then a few drugs can be administered endotracheally. These drugs are atropine, lidocaine, epinephrine, naloxone, and vasopressin.[8] Medications administered through the endotracheal route however, will have both a lower and delayed peak concentration than when they are administered by the IV or IO routes.[8] Furthermore, clinical trials have failed to demonstrate any benefit with using the endotracheal route.[119,120] In fact, one clinical trial noted lower rates of ROSC [15% vs 27%, $P \leq 0.01$], hospital admission [9% vs 20%, $P \leq 0.02$] and hospital discharge [0% vs 5%, $P \leq 0.02$] with endotracheal drug administration compared to IV.[120] Currently, the recommended endotracheal dose is 2 to 2.5 times larger than the IV/IO dose.[8] Given the unpredictable absorption and the lack of clinical effectiveness though, either the IV or IO routes are preferred.

ETHICAL AND ECONOMICAL CONSIDERATIONS

The primary endpoint of CPR is to survive to hospital discharge with good neurologic function. Simply surviving to hospital discharge, but in a vegetative or comatose state, can not be considered a favorable outcome and can impose a tremendous economic burden on the healthcare system. Additionally, most patients would choose not to continue living in this state and would have preferred withdrawal of support.[121] One difficulty in making these decisions is defining medical futility. The two major determinants of medical futility are length of life and quality of life.[8] An intervention that cannot increase length or quality of life is considered futile. Ethically, health care providers are obligated to respect patient autonomy, which is easiest in the arrest situation if the patient has an advance directive. If the patient loses the ability to make informed decisions regarding medical care, then a spouse or a designated healthcare advocate must act as a surrogate decision maker, invoking what has been termed substituted judgment: following the predetermined wishes of the patient.

Many health care professionals have attempted to identify patients unlikely to benefit from cardiac resuscitation. One study evaluated 2 termination rules for resuscitation following out-of-hospital arrest.[122] The first was the BLS rule which consisted of (1) the event was not witnessed by EMS personnel, (2) no AED was used or manual shock applied and (3) ROSC was not achieved in the out-of-hospital setting. The second rule was the advanced life support rule which consisted of the BLS criteria plus (1) the arrest was not witnessed by a bystander and (2) no bystander CPR administered. These rules accurately identified patients who were unlikely to benefit from rapid transport to a hospital with a positive predictive value of 0.998 (BLS rule) and 1.000 (ALS rule).

If the patient survives to hospital admission, guidelines from the American Academy of Neurology are available to aid in the decisions relative to outcome prediction for comatose survivors of cardiac arrest.[123] Collectively, these factors could improve the cost-effectiveness of CPR programs and decrease the economic burden of cardiac arrest to the healthcare system.

EVALUATION OF THERAPEUTIC OUTCOMES

To measure the success of resuscitation outcomes, therapeutic outcome monitoring should occur both during the resuscitation attempt and in the postresuscitation phase. The optimal outcome following CPR is an awake, responsive, spontaneously breathing patient. Patients must remain neurologically intact with minimal morbidity following the resuscitation if it is to be truly classified as a success.

Unfortunately, there are no reliable criteria for clinicians to use to gauge the efficacy of CPR. Nonetheless, heart rate, cardiac rhythm, and blood pressure should be assessed and documented throughout the resuscitation attempt and subsequent to each intervention. Coronary perfusion pressure (CPP = aortic diastolic pressure minus right atrial diastolic pressure) should be assessed in patients whom intra-arterial monitoring is in place. Determination of the presence or absence of a pulse is paramount to deciding which interventions may be appropriate. Palpating a pulse to determine the efficacy of blood flow during CPR has not been shown to be useful, however.

End-tidal carbon dioxide monitoring is a safe and effective method to assess cardiac output during CPR and has been associated with ROSC.[8] The main determinant for carbon dioxide excretion is the rate of delivery from the peripheral sites (where it is produced) to the lungs. Increasing cardiac output (through effective CPR) will yield higher end-tidal carbon dioxide levels as delivery of carbon dioxide to the lungs increases.

Clinicians should also consider the precipitating cause of the cardiac arrest, such as an MI, electrolyte imbalance, or primary arrhythmia. Pre-arrest status should be carefully reviewed, particularly if the patient was receiving drug therapy. Altered cardiac, hepatic, and renal function resulting from ischemic damage during the cardiopulmonary arrest warrant special attention and may require advanced care. Neurologic function should be assessed by means of the Cerebral Performance Category and the Glasgow Coma Scale.[124,125] Nonresponse to an array of suitable interventions may indicate that resuscitation is impossible.

CLINICAL CONTROVERSIES

1. The concept of CCR has led to an alternative treatment approach for cardiac arrest that some clinicians feel is superior to that proposed by the AHA.

2. Some clinicians feel that vasopressin offers substantial benefit to patients following cardiac arrest while others feel it has no advantage over epinephrine alone.
3. Although amiodarone is considered the preferred antiarrhythmic in patients with VF/PVT, there is conflicting data regarding its effect on outcome when compared to lidocaine.
4. Some clinicians support the use of therapeutic hypothermia for all comatose patients following cardiac arrest while others recommend its use only after arrests due to VF.

ABBREVIATIONS

ACLS: advanced cardiac life support
AED: automated external defibrillator
AHA: American Heart Association
BLS: basic life support
CCR: cardiocerebral resuscitation
CI: confidence interval
CPP: coronary perfusion pressure
CPR: cardiopulmonary resuscitation
ECC: emergency cardiovascular care
ECMO: extracorporeal membrane oxygenation
EMS: emergency medical services
IO: intraosseous
IV: intravenous
LVAD: left ventricular assist device
MI: myocardial infarction
OR: odds ratio
PCI: percutaneous coronary intervention
PEA: pulseless electrical activity
PE: pulmonary embolism
ROSC: return of spontaneous circulation
PVT: pulseless ventricular tachycardia
VF: ventricular fibrillation

CLINICAL PRESENTATION

Symptoms

- Anxiety, change in mental status or unconscious
- Cold, clammy extremities
- Dyspnea, shortness of breath or no respiration
- Chest pain
- Diaphoresis
- Nausea and vomiting

Signs

- Hypotension
- Tachycardia, bradycardia, irregular or no pulse
- Cyanosis
- Hypothermia

CHAPTER 19

Hypertension

JOSEPH J. SASEEN AND ERIC J. MACLAUGHLIN

KEY CONCEPTS

1. The risk of cardiovascular (CV) morbidity and mortality is directly correlated with blood pressure (BP).
2. Outcome trials have shown that antihypertensive drug therapy substantially reduces the risks of CV events and death in patients with high BP.
3. Essential hypertension is usually an asymptomatic disease. A diagnosis cannot be made based on one elevated BP measurement. An elevated value from the average of two or more measurements, present during two or more clinical encounters, is needed to diagnose hypertension.
4. The overall goal of treating hypertension is to reduce hypertension-associated morbidity and mortality from CV events. These are considered hypertension-associated complications. The selection of specific drug therapy is based on evidence that demonstrates CV risk reduction.
5. A goal BP of less than 140/90 mm Hg is appropriate for general prevention of CV events and CV risk reduction. A lower goal BP of less than 130/80 mm Hg is recommended for patients with diabetes and significant chronic kidney disease. However, recommendations from the American Heart Association also recommend this lower goal BP of less than 130/80 mm Hg for patients with known coronary artery disease [myocardial infarction (MI), stable angina, unstable angina], noncoronary atherosclerotic vascular disease (ischemic stroke, transient ischemic attack, peripheral arterial disease, abdominal aortic aneurysm) or a 10% or greater 10 year risk of fatal coronary heart disease or nonfatal MI based on Framingham risk scoring.
6. Magnitude of BP elevation should be used to guide determination of the number of agents to start when implementing drug therapy. Most patients with Stage 1 hypertension should be started on one drug, with the option of starting two for some patients. However, most patients presenting with Stage 2 hypertension should be started on two drugs.
7. Lifestyle modifications should be prescribed in all patients, especially those with prehypertension and hypertension. However, they should never be used as a replacement for antihypertensive drug therapy for patients with hypertension, especially in those with additional CV risk factors.
8. Thiazide-type diuretics, angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARB), and calcium channel blockers (CCB) are all considered first-line agents for most patients with hypertension for general prevention of CV events and CV risk reduction. These first-line options are for patients with hypertension that do not have any compelling indications for a specific antihypertensive drug class.
9. For general prevention of CV events and CV risk reduction in most patients with hypertension, β-blockers do not reduce CV events to the extent as thiazide-type diuretics, ACE inhibitors, ARBs, or CCBs.
10. Compelling indications are comorbid conditions where specific antihypertensive drug classes have been shown in outcome trials to provide unique long-term benefits (reducing the risk of CV events).
11. Patients with diabetes are at high risk for CV events. All patients with diabetes and hypertension should be managed with either an ACE inhibitor or an ARB. These are typically in combination with one or more other antihypertensive agents because multiple agents frequently are needed to control BP.
12. Older patients with isolated systolic hypertension are often at risk for orthostatic hypotension when antihypertensive drug therapy is started, particularly with diuretics, ACE inhibitors, and ARBs. Although overall antihypertensive drug therapy should be the same, low initial doses should be used and dosage titrations should be gradual to minimize risk of orthostatic hypotension.
13. Alternative antihypertensive agents have not been proven to reduce the risk of CV events compared with first-line antihypertensive agents. They should be used primarily in combination with first-line agents to provide additional BP lowering.
14. Initial therapy with the combination of two antihypertensive agents should be used in most patients presenting with stage 2 hypertension. This is also an option for patients presenting with stage 1 hypertension. Most patients require combination therapy to achieve goal BP values.
15. Patients are considered to have resistant hypertension when they fail to attain goal BP values while adherent to a regimen that includes at least three agents at maximum dose, one of which includes a diuretic.
16. Hypertensive urgency is ideally managed by adjusting maintenance therapy (adding a new antihypertensive and/or increasing the dose of a present medication). This provides a gradual reduction in BP, which is a safer treatment approach than rapid reductions in BP.

Hypertension is a common disease that is simply defined as persistently elevated arterial blood pressure (BP). Although elevated BP was perceived to be "essential" for adequate perfusion of vital organs during the early and middle 1900s, it is now identified as one of the most significant risk factors for cardiovascular (CV) disease in the United States. Increasing awareness and diagnosis of hypertension, and improving control of BP with appropriate treatment, are considered critical public health initiatives to reduce CV morbidity and mortality.

The Seventh report of the Joint National Committee on the Detection, Evaluation, and Treatment of High Blood Pressure (JNC7) is the most prominent evidence-based clinical guideline in United States for the management of hypertension,[1] supplemented by the 2007 American Heart Association (AHA) Scientific Statement on the treatment of hypertension.[2] This chapter reviews relevant components of both these guidelines and additional evidence from clinical trials, with a focus on the pharmacotherapy of hypertension. The Eight report of the Joint National Committee (JNC8) will represent the most updated treatment guideline, although publication is not expected until 2011.

The National Health and Nutrition Examination Survey and the National Center for Health Statistics regularly assess hypertension in the United States.[3] Data from 2003 to 2006 indicate that of the population of Americans with hypertension, 77.6% are aware that they have hypertension, only 67.9% are on some form of antihypertensive treatment, and only 44.1% of all patients have controlled BP. This control rate is substantially higher than in the past. However, there remain many opportunities for clinicians to improve the care of patients with hypertension.

EPIDEMIOLOGY

Approximately 31% of Americans (74.5 million people) have elevated BP, defined as greater than or equal to 140/90 mm Hg.[3] The overall incidence is similar between men and women, but varies depending on age. The percentage of men with high BP is higher than for women before the age of 45 and is similar to that of women between the ages 45 and 64. However, after the age of 64, a much higher percentage of women have high BP than men.[3] Prevalence rates are highest in non-Hispanic blacks (45% in women, 44% in men), followed by non-Hispanic whites (31% in women, 34% in men), Mexican Americans (32% in women, 26% in men), American Indians/Alaska Natives (25% in women and men), and Asians (21% in women and men).[3]

BP values increase with age, and hypertension (persistently elevated BP values) is very common in the elderly. The lifetime risk of developing hypertension among those 55 years of age and older who are normotensive is 90%.[1] Most patients have prehypertension before they are diagnosed with hypertension, with most diagnoses occurring between the third and fifth decades of life.

ETIOLOGY

In most patients, hypertension results from unknown pathophysiological etiology (*essential* or *primary hypertension*). This form of hypertension cannot be cured, but it can be controlled. A small percentage of patients have a specific cause of their hypertension (*secondary hypertension*). There are many potential secondary causes that either are concurrent medical conditions or are endogenously induced. If the cause can be identified, hypertension in these patients can be mitigated or potentially be cured.

ESSENTIAL HYPERTENSION

Over 90% of individuals with high BP have essential hypertension.[1] Numerous mechanisms have been identified that may contribute to the pathogenesis of this form of hypertension, so identifying the exact underlying abnormality is not possible. Genetic factors may play an important role in the development of essential hypertension. There are monogenic and polygenic forms of BP dysregulation that may be responsible for essential hypertension.[4] Many of these genetic traits feature genes that affect sodium balance, but genetic mutations altering urinary kallikrein excretion, nitric oxide release, and excretion of aldosterone, other adrenal steroids, and angiotensinogen are also documented.[4] In the future, genetic testing for these traits could lead to alternative approaches to preventing or treating hypertension; however, this is not currently recommended.

SECONDARY HYPERTENSION

Fewer than 10% of patients have secondary hypertension where either a comorbid disease or drug (or other product) is responsible for elevating BP (see Table 19–1).[1,5] In most of these cases, renal dysfunction resulting from severe chronic kidney disease or renovascular disease is the most common secondary cause. Certain drugs (or other products), either directly or indirectly, can cause hypertension or exacerbate hypertension by increasing BP. The most common agents are listed in Table 19–1. When a secondary cause is identified, removing the offending agent (when feasible) or treating/correcting the underlying comorbid condition should be the first step in management.

PATHOPHYSIOLOGY[4,6]

Multiple factors that control BP are potential contributing components in the development of essential hypertension. These include malfunctions in either humoral [i.e., the renin-angiotensin-aldosterone system (RAAS)] or vasodepressor mechanisms, abnormal neuronal mechanisms, defects in peripheral autoregulation, and disturbances in sodium, calcium, and natriuretic hormone. Many of these factors are cumulatively affected by the multifaceted RAAS, which ultimately regulates arterial BP. It is probable that no one factor is solely responsible for essential hypertension.

ARTERIAL BP

Arterial BP is the pressure in the arterial wall measured in millimeters of mercury (mm Hg). The two typical arterial BP values are *systolic BP* (SBP) and *diastolic BP* (DBP). SBP represents the peak value, which is achieved during cardiac contraction. DBP is achieved after contraction when the cardiac chambers are filling, and represents the nadir value. The difference between SBP and DBP is called the pulse pressure and is a measure of arterial wall tension. Mean arterial pressure (MAP) is the average pressure throughout the cardiac cycle of contraction. It is sometimes used clinically to represent overall arterial BP, especially in hypertensive emergency. During a cardiac cycle, two-thirds of the time is spent in diastole and one-third in systole. Therefore, the MAP is calculated by using the following equation:

$$MAP = (SBP \times 1/3) + (DBP \times 2/3)$$

Arterial BP is hemodynamically generated by the interplay between blood flow and the resistance to blood flow. It is mathematically defined as the product of cardiac output (CO)

TABLE 19-1 Secondary Causes of Hypertension[1,5]

Disease	Drugs and Other Products Associated with Hypertension[a]
Chronic kidney disease Cushing syndrome Coarctation of the aorta Obstructive sleep apnea Parathyroid disease Pheochromocytoma Primary aldosteronism Renovascular disease Thyroid disease	**Prescription drugs** • Amphetamines (amphetamine, dexmethylphenidate, dextroamphetamine, lisdexamfetamine, methylphenidate, phendimetrazine, phentermine) and anorexiants (sibutramine) • Anti-vascular endothelin growth factor agents (bevacizumab, sorafenib, sunitinib) • Corticosteroids (cortisone, dexasmethasone, fludrocortisone, hydrocortisone, methylprednisolone, prednisolone, prednisone, triamcinolone • Calcineurin inhibitors (cyclosporine, tacrolimus) • Decongestants (pseudoephedrine, phenylephrine) • Ergot alkaloids (ergonovine, methysergide) • Erythropoiesis stimulating agents (erythropoetin, darbopoetin) • Estrogen-containing oral contraceptives • Nonsteroidal antiinflammatory drugs–Cyclooxygenase-2 selective (celecoxib) and nonselective (aspirin, choline magnesium trisalicylate, diclofenac, diflunisal, etodolac, fenoprofen, flurbiprofen, ibuprofen, indomethacin, ketoprofen, ketorolac, meclofenamate, mefenamic acid, meloxicam, nabumetone, naproxen, naproxen sodium, oxaprozin, piroxicam, salsalate, sulindac, tolmetin) • Others: Desvenlafaxine, venlafaxine, bupropion Situations: β-blocker or centrally acting α agonists (when adruptly discontinued); β-blocker without α-blocker first when treating pheochromocytoma; use of a monoamine oxidase inhibitor (isocarboxazid, phenelzine, tranylcypromine) with tryamine containing foods or certain drugs **Street drugs and other products** Cocaine and cocaine withdrawal Ephedra alkaloids (e.g., Ma huang), "herbal ecstasy," other analogues Nicotine and withdrawal, anabolic steroids, narcotic withdrawal, ergot-containing herbal products, St. John's wort **Food substances** Sodium Ethanol Licorice

[a]Agents of most clinical importance.

and total peripheral resistance (TPR) according to the following equation:

$$BP = CO \times TPR$$

CO is the major determinant of SBP, whereas TPR largely determines DBP. In turn, CO is a function of stroke volume, heart rate, and venous capacitance. Table 19–2 lists physiologic causes of increased CO and TPR and correlates them to potential mechanisms of pathogenesis.

Under normal physiologic conditions, arterial BP fluctuates throughout the day following a circadian rhythm. BP decreases to its lowest daily values during sleep followed by a sharp rise starting a few hours prior to awakening with the highest values occurring midmorning. BP is also increased acutely during physical activity or emotional stress.

TABLE 19-2 Potential Mechanisms of Pathogenesis

Blood pressure (BP) is the mathematical product of cardiac output and peripheral resistance. Elevated BP can result from increased cardiac output and/or increased total peripheral resistance.

Increased cardiac output	Increased cardiac preload: • Increased fluid volume from excess sodium intake or renal sodium retention (from reduced number of nephrons or decreased glomerular filtration) Venous constriction: • Excess stimulation of the renin-angiotensin aldosterone system (RAAS) • Sympathetic nervous system overactivity
Increased peripheral resistance	Functional vascular constriction: • Excess stimulation of the RAAS • Sympathetic nervous system overactivity • Genetic alterations of cell membranes • Endothelial-derived factors Structural vascular hypertrophy: • Excess stimulation of the RAAS • Sympathetic nervous system overactivity • Genetic alterations of cell membranes • Endothelial-derived factors • Hyperinsulinemia resulting from the metabolic syndrome

Classification

The JNC7 classification of BP in adults (age greater than or equal to 18) is based on the average of 2 or more properly measured BP values from 2 or more clinical encounters (Table 19–3).[1] It includes 4 categories: normal, prehypertension, Stage 1 hypertension, and Stage 2 hypertension. Prehypertension is not considered a disease category but identifies patients whose BP is likely to increase into the classification of hypertension in the future.

Hypertensive crises are clinical situations where BP values are very elevated, typically greater than 180/120 mm Hg.[6] They are categorized as either *hypertensive emergency* or *hypertensive urgency*. Hypertensive emergencies are extreme elevations in BP that are accompanied by acute or progressing target-organ damage. Hypertensive urgencies are high elevations in BP without acute or progressing target-organ injury.

Cardiovascular Risk and Blood Pressure

1 Epidemiologic data clearly indicate a strong correlation between BP and CV morbidity and mortality.[7] Risk of stroke, myocardial infarction (MI), angina, heart failure, kidney failure, or early death from a CV cause are directly correlated with BP. Starting at a BP of 115/75, risk of CV disease doubles with every 20/10 mm Hg increase.[1] Even patients with prehypertension have an increased risk of CV disease.

TABLE 19-3 Classification of Blood Pressure in Adults (Age ≥18 Years)[a]

Classification	Systolic Blood Pressure (mm Hg)		Diastolic Blood Pressure (mm Hg)
Normal	Less than 120	and	Less than 80
Prehypertension[b]	120–139	or	80–89
Stage 1 hypertension	140–159	or	90–99
Stage 2 hypertension	≥160	or	≥100

[a]Classification determined based on the average of two or more properly measured seated BP values from two or more clinical encounters. If systolic and diastolic BP values yield different classifications, the highest category is used for the purpose of determining a classification.
[b]For certain patients, BP values within the prehypertension range are considered above goal (see Box 19–2).

❷ Treating patients with hypertension with antihypertensive drug therapy provides significant clinical benefits. Large-scale placebo-controlled outcome trials have shown that the increased risks of CV events and death associated with elevated BP are reduced substantially by antihypertensive therapy.[8–11] This is discussed in the Treatment Section.

SBP is a stronger predictor of CV disease than DBP in adults ≥50 years and is the most important clinical BP parameter for most patients.[1] Patients are considered to have *isolated systolic hypertension* when their SBP values are elevated (greater than or equal to 140 mm Hg) and DBP values are not (less than 90 mm Hg, but commonly less than 80 mm Hg). Isolated systolic hypertension is believed to result from pathophysiologic changes in the arterial vasculature consistent with aging. These changes decrease the compliance of the arterial wall and portend an increased risk of CV morbidity and mortality. The elevated pulse pressure (SBP minus DBP) is believed to reflect extent of atherosclerotic disease in the elderly and is a measure of increased arterial stiffness. Higher pulse pressure values seen in those with isolated systolic hypertension are correlated with an increased risk of CV mortality.

HUMORAL MECHANISMS

Several humoral abnormalities involving the RAAS, natriuretic hormone, and hyperinsulinemia may be involved in the development of essential hypertension.

The Renin-Angiotensin-Aldosterone System (RAAS)

The RAAS is a complex endogenous system that is involved with most regulatory components of arterial BP. Activation and regulation are primarily governed by the kidney (see Fig. 19–1). The RAAS regulates sodium, potassium, and blood volume. Therefore, this system significantly influences vascular tone and sympathetic nervous system activity and is the most influential contributor to the homeostatic regulation of BP.

Renin is an enzyme that is stored in the juxtaglomerular cells, which are located in the afferent arterioles of the kidney. The release of renin is modulated by several factors: intrarenal factors (e.g., renal perfusion pressure, catecholamines, angiotensin II), and extrarenal factors (e.g., sodium, chloride, and potassium).

Juxtaglomerular cells function as a baroreceptor-sensing device. Decreased renal artery pressure and kidney blood flow is sensed by these cells and stimulate secretion of renin. The juxtaglomerular apparatus also includes a group of specialized distal tubule cells referred to collectively as the *macula densa.* A decrease in sodium and chloride delivered to the distal tubule stimulates renin release. Catecholamines increase renin release probably by directly stimulating sympathetic nerves on the afferent arterioles that in turn activate the juxtaglomerular cells.

Renin catalyzes the conversion of angiotensinogen to angiotensin I in the blood. Angiotensin I is then converted to angiotensin II by angiotensin-converting enzyme (ACE). After binding to specific

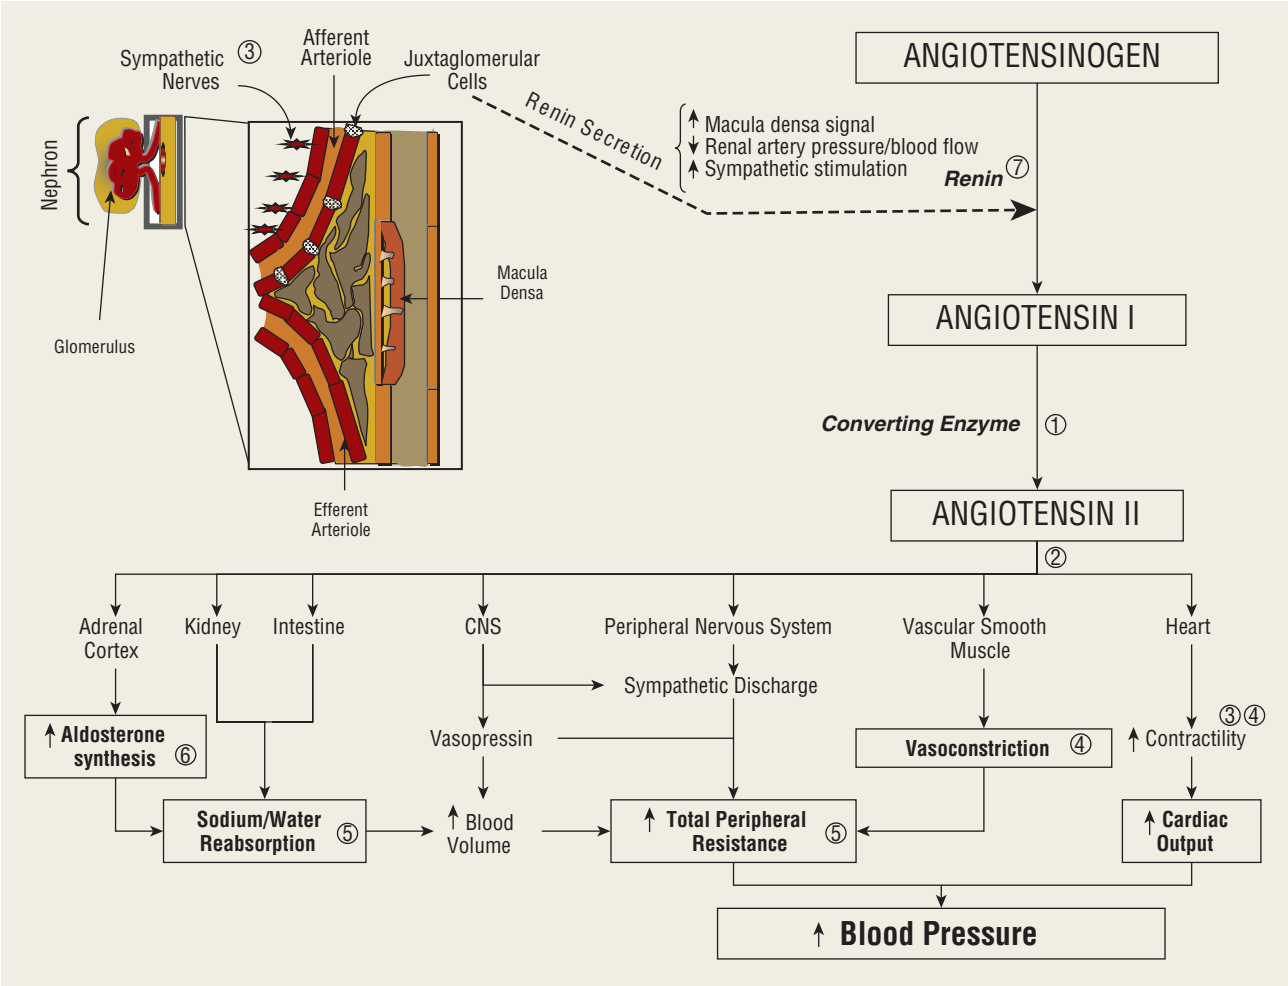

FIGURE 19-1. Diagram representing the renin-angiotensin-aldosterone system. The interrelationship between the kidney, angiotensin II, and regulation of blood pressure are depicted. Renin secretion from the juxtaglomerular cells in the afferent arterioles is regulated by three major factors to trigger conversion of angiotensinogen to angiotensin 1. The primary sites of action for major antihypertensive agents are included: ① ACE inhibitors; ② angiotensin II receptor blockers; ③ β-blockers; ④ calcium channel blockers; ⑤ diuretics; ⑥ aldosterone antagonists; ⑦ direct renin inhibitor.

receptors (classified as either AT_1 or AT_2 subtypes), angiotensin II exerts biologic effects in several tissues. The AT_1 receptor is located in brain, kidney, myocardium, peripheral vasculature, and the adrenal glands. These receptors mediate most responses that are critical to CV and kidney function. The AT_2 receptor is located in adrenal medullary tissue, uterus, and brain. Stimulation of the AT_2 receptor does not influence BP regulation.

Circulating angiotensin II can elevate BP through pressor and volume effects. Pressor effects include direct vasoconstriction, stimulation of catecholamine release from the adrenal medulla, and centrally mediated increases in sympathetic nervous system activity. Angiotensin II also stimulates aldosterone synthesis from the adrenal cortex. This leads to sodium and water reabsorption that increases plasma volume, TPR, and ultimately BP. Aldosterone also has a deleterious role in the pathophysiology of other CV diseases (heart failure, MI, and kidney disease) by promoting tissue remodeling leading to myocardial fibrosis and vascular dysfunction. Clearly, any disturbance in the body that leads to activation of the RAAS could explain chronic hypertension.

The heart and brain contain a local RAAS. In the heart, angiotensin II is also generated by angiotensin I convertase (human chymase). This enzyme is not blocked by ACE inhibition. Activation of the myocardial RAAS increases cardiac contractility and stimulates cardiac hypertrophy. In the brain, angiotensin II modulates the production and release of hypothalamic and pituitary hormones, and enhances sympathetic outflow from the medulla oblongata.

Natriuretic Hormone

Natriuretic hormone inhibits sodium and potassium-ATPase and thus interferes with sodium transport across cell membranes. Inherited defects in the kidney's ability to eliminate sodium can cause an increased blood volume. A compensatory increase in the concentration of circulating natriuretic hormone theoretically could increase urinary excretion of sodium and water. However, this hormone might block the active transport of sodium out of arteriolar smooth muscle cells. The increased intracellular sodium concentration ultimately would increase vascular tone and BP.

Insulin Resistance and Hyperinsulinemia

The development of hypertension and associated metabolic abnormalities is referred to as the metabolic syndrome.[12] Hypothetically, increased insulin concentrations may lead to hypertension because of increased renal sodium retention and enhanced sympathetic nervous system activity. Moreover, insulin has growth hormone–like actions that can induce hypertrophy of vascular smooth muscle cells. Insulin also may elevate BP by increasing intracellular calcium, which leads to increased vascular resistance. The exact mechanism by which insulin resistance and hyperinsulinemia occur in hypertension is unknown. However, this association is strong because many of the criteria used to define this population (i.e., elevated BP, abdominal obesity, dyslipidemia, and elevated fasting glucose) are often present in patients with hypertension.[12]

NEURONAL REGULATION

Central and autonomic nervous systems are intricately involved in the regulation of arterial BP. Many receptors that either enhance or inhibit norepinephrine release are located on the presynaptic surface of sympathetic terminals. The alpha (α) and beta (β) presynaptic receptors play a role in negative and positive feedback to the norepinephrine-containing vesicles. Stimulation of presynaptic α-receptors (α_2) exerts a negative inhibition on norepinephrine release. Stimulation of presynaptic β-receptors facilitates norepinephrine release.

Sympathetic neuronal fibers located on the surface of effector cells innervate the α- and β-receptors. Stimulation of postsynaptic α-receptors (α_1) on arterioles and venules results in vasoconstriction. There are two types of postsynaptic β-receptors, β_1 and β_2. Both are present in all tissue innervated by the sympathetic nervous system. However, in some tissues β_1-receptors predominate, and in other tissues β_2-receptors predominate. Stimulation of β_1-receptors in the heart results in an increase in heart rate and contractility, whereas stimulation of β_2-receptors in the arterioles and venules causes vasodilatation.

The baroreceptor reflex system is the major negative-feedback mechanism that controls sympathetic activity. Baroreceptors are nerve endings lying in the walls of large arteries, especially in the carotid arteries and aortic arch. Changes in arterial BP rapidly activate baroreceptors that then transmit impulses to the brain stem through the ninth cranial nerve and vagus nerves. In this reflex system, a decrease in arterial BP stimulates baroreceptors, causing reflex vasoconstriction and increased heart rate and force of cardiac contraction. These baroreceptor reflex mechanisms may be less responsive in the elderly and those with diabetes.

Stimulation of certain areas within the central nervous system (nucleus tractus solitarius, vagal nuclei, vasomotor center, and the area postrema) can either increase or decrease BP. For example, α_2-adrenergic stimulation within the central nervous system decreases BP through an inhibitory effect on the vasomotor center. However, angiotensin II increases sympathetic outflow from the vasomotor center, which increases BP.

The purpose of these neuronal mechanisms is to regulate BP and maintain homeostasis. Pathologic disturbances in any of the four major components (autonomic nerve fibers, adrenergic receptors, baroreceptors, central nervous system) could chronically elevate BP. These systems are physiologically interrelated. A defect in one component may alter normal function in another. Therefore, cumulative abnormalities may explain the development of essential hypertension.

PERIPHERAL AUTOREGULATORY COMPONENTS

Abnormalities in renal or tissue autoregulatory systems could cause hypertension. It is possible that a renal defect in sodium excretion may develop, which can then cause resetting of tissue autoregulatory processes resulting in a higher BP. The kidney usually maintains a normal BP through a volume-pressure adaptive mechanism. When BP drops, the kidneys respond by increasing retention of sodium and water, which leads to plasma volume expansion that increases BP. Conversely, when BP rises above normal, renal sodium and water excretion are increased to reduce plasma volume and CO.

Local autoregulatory processes maintain adequate tissue oxygenation. When tissue oxygen demand is normal to low, the local arteriolar bed remains relatively vasoconstricted. However, increases in metabolic demand triggers arteriolar vasodilation that lowers peripheral vascular resistance and increases blood flow and oxygen delivery through autoregulation.

Intrinsic defects in these renal adaptive mechanisms could lead to plasma volume expansion and increased blood flow to peripheral tissues, even when BP is normal. Local tissue autoregulatory processes that vasoconstrict would then be activated to offset the increased blood flow. This effect would result in increased peripheral vascular resistance and, if sustained, would also result in thickening of the arteriolar walls. This pathophysiological component is plausible because increased TPR is a common underlying finding in patients with essential hypertension.

VASCULAR ENDOTHELIAL MECHANISMS

Vascular endothelium and smooth muscle play important roles in regulating blood vessel tone and BP. These regulating functions are mediated by vasoactive substances that are synthesized by endothelial cells. It has been postulated that a deficiency in the local synthesis of vasodilating substances (prostacyclin and bradykinin) or excess vasoconstricting substances (angiotensin II and endothelin I) contribute to essential hypertension, atherosclerosis, and other CV diseases.

Nitric oxide is produced in the endothelium, relaxes the vascular epithelium, and is a very potent vasodilator. The nitric oxide system is an important regulator of arterial BP. Patients with hypertension may have an intrinsic nitric oxide deficiency, resulting in inadequate vasodilatation.

ELECTROLYTES

Epidemiologic and clinical data have associated excess sodium intake with hypertension. Population-based studies indicate that high sodium diets are associated with a high prevalence of stroke and hypertension. Conversely, low sodium diets are associated with a low prevalence of hypertension. Clinical studies have consistently shown that dietary sodium restriction lowers BP in many (but not all) patients with elevated BP. The exact mechanisms by which excess sodium leads to hypertension are not known.

Altered calcium homeostasis also may play an important role in the pathogenesis of hypertension. A lack of dietary calcium hypothetically can disturb the balance between intracellular and extracellular calcium, resulting in an increased intracellular calcium concentration. This imbalance can alter vascular smooth muscle function by increasing peripheral vascular resistance. Some studies have shown that dietary calcium supplementation results in a modest BP reduction for patients with hypertension.

The role of potassium fluctuations is also inadequately understood. Potassium depletion may increase peripheral vascular resistance, but the clinical significance of small serum potassium concentration changes is unclear. Furthermore, data demonstrating reduced CV risk with dietary potassium supplementation are very limited.

CLINICAL PRESENTATION

The clinical presentation of hypertension is described in Box 19–1.

BOX 19-1 CLINICAL PRESENTATION OF HYPERTENSION

General: the patient may appear healthy or may have the presence of additional CV risk factors:

- Age (greater than or equal to 55 for men, greater than or equal to 65 for women)
- Diabetes mellitus
- Dyslipidemia
- Microalbuminuria
- Family history of premature CV disease
- Obesity (body mass index greater than or equal to 30 kg/m^2)
- Physical inactivity
- Tobacco use

Symptoms: Usually none related to elevated BP.

Signs: Previous BP values in either the prehypertension or the hypertension category.

Laboratory Tests: BUN/serum creatinine, fasting lipid panel, fasting blood glucose, serum electrolytes (sodium, potassium), spot urine albumin-to-creatinine ratio. The patient may have normal values and still have hypertension. However, some may have abnormal values that are consistent with either additional CV risk factors or hypertension-related damage.

Other Diagnostic Tests: 12-lead electrocardiogram, estimated glomerular filtration rate [using modification of diet in renal disease (MDRD) equation].

Hypertension-Related Target-Organ Damage: The patient may have a previous medical history or diagnostic findings that indicate the presence of hypertension-related target-organ damage:

- Brain (stroke, transient ischemic attack, dementia)
- Eyes (retinopathy)
- Heart (left ventricular hypertrophy, angina, prior MI, prior coronary revascularization, heart failure)
- Kidney (chronic kidney disease)
- Peripheral vasculature (peripheral arterial disease)

DIAGNOSTIC CONSIDERATIONS

3 Hypertension is termed the *silent killer* because most patients do not have symptoms. The primary physical finding is elevated BP. The diagnosis of hypertension cannot be made based on one elevated BP measurement. The average of two or more measurements taken during two or more clinical encounters should be used to diagnose hypertension.[1] This BP average should be used to establish a diagnosis, and then classify the stage of hypertension using Table 19–3.

Measuring BP

The measurement of BP is a common routine medical screening tool that should be conducted at every healthcare encounter.[1]

Cuff Measurement Using Sphygmomanometry[13] The most common procedure to measure BP in clinical practice is the indirect measurement of BP using sphygmomanometry. The appropriate procedure to indirectly measure BP using sphygmomanometry has been described by the AHA.[13] It is imperative that the measurement equipment (inflation cuff, stethoscope, and manometer) meet certain national standards to ensure maximum quality and precision with measurement.

The AHA stepwise technique is recommended:

- Patients should ideally refrain from nicotine and caffeine ingestion for 30 minutes and sit with lower back supported in a chair. Bare arm should be supported and resting near heart level. Feet should be flat on the floor (with legs not crossed). The measurement environment should be relatively quiet and provide privacy. Measuring BP in a position other than seated (supine or standing position) may be required under special circumstances (suspected orthostatic hypotension, or dehydration).
- Measurement should begin only after a 5-minute period of rest.
- A properly sized cuff (pediatric, small, regular, large, or extra large) should be used. The inflatable rubber bladder inside the cuff should cover at least 80% of the arm of the upper arm circumference and 40% of the upper arm width.
- The palpatory method should be used to estimate the SBP:
  - Place the cuff on the upper arm 2 to 3 cm above the antecubital fossa and attach it to the manometer (either a mercury or aneroid).

- Close the inflation valve and inflate the cuff to 70 mm Hg.
- Palpate the radial pulse with the index and middle fingers of the opposite hand.
- Inflate further in increments of 10 mm Hg until the radial pulse is no longer palpated.
- Note the pressure at which the radial pulse is no longer palpated; this is the estimated SBP.
- Release the pressure in the cuff by opening the value.

- The bell (not the diaphragm) of the stethoscope should be placed on the skin of the antecubital fossa, directly over where the brachial artery is palpated. The stethoscope earpieces should be inserted appropriately. The valve should be closed with the cuff then inflated to 30 mm Hg above the estimated SBP from the palpatory method. The value should be slightly opened to slowly release pressure at a rate of 2 to 3 mm Hg/second.
- The clinician should listen for Korotkoff sounds with the stethoscope. The first phase of Korotkoff sounds are the initial presence of clear tapping sounds. Note the pressure at the first recognition of these sounds. This is the SBP. As pressure deflates, note the pressure when all sounds disappear, right at the last sound. This is the DBP.
- Measurements should be rounded to the nearest 2 mm Hg.
- A second measurement should be obtained after at least 1 minute. If these values differ by more than 5 mm Hg, additional measurements should be obtained.
- Neither the patient nor the observer should talk during measurement.
- When first establishing care with a patient, BP should be measured in both arms. If consistent inter-arm differences exist, the arm with the higher value should be used.

Inaccuracies with indirect measurements result from inherent biological variability of BP, inaccuracies related to suboptimal technique, and the white coat effect.[13] Variations in BP occur with environmental temperature, the time of day and year, meals, physical activity, posture, alcohol, nicotine, and emotions. In the clinic setting, standard BP measurement procedures (e.g., appropriate rest period, poor technique, minimal number of measurements) are often not followed, which results in poor estimation of true BP. It is recommended that the stethoscope bell, rather than the diaphragm, be used for measurement, though some studies suggest little difference between two.[13]

Approximately 15% to 20% of patients have *white coat hypertension,* where BP values rise in a clinical setting but return to normal in nonclinical environments using home or ambulatory BP measurements.[13] Interestingly, the rise in BP dissipates gradually over several hours after leaving the clinical setting. It may or may not be precipitated by other stresses in the patient's daily life. This is in contrast to *masked hypertension,* where a decrease in BP occurs in the clinical setting.[14] With masked hypertension, home BP is hypertensive, while the in-office BP is normotensive or substantially lower than at home. This situation may lead to under treatment or lack of treatment for hypertension. Moreover, patients with either white coat or masked hypertension have a high risk of progressing to develop sustained hypertension, which can result in a higher risk of CV events compared with normotensive patients.[15]

Pseudohypertension is a falsely elevated BP measurement. It may be seen in the elderly, those with long-standing diabetes, or those with chronic kidney disease due to rigid, calcified brachial arteries.[13] In these patients, the true arterial BP when measured directly with intraarterial measurement (the most accurate measurement of BP) is much lower than that measured using the indirect cuff method. The Osler maneuver can be used to test for pseudohypertension. In this maneuver, the BP cuff is inflated above peak SBP. If the radial artery remains palpable, the patient has a positive Osler sign (rigid artery), which may indicate pseudohypertension.

Elderly patients with a wide pulse pressure may have an auscultatory gap that can lead to underestimated SBP or overestimated DBP measurements.[13] In this situation, as the cuff pressure falls from the true SBP value, the Korotkoff sound may disappear (indicating a false DBP measurement), reappear (a false SBP measurement), and then disappear again at the true DBP value. When an auscultatory gap is present, Korotkoff sounds are usually heard when pressure in the cuff first starts to decrease after inflation. This may be eliminated by raising the arm overhead by 30 seconds before bringing it to the proper position and inflating the cuff. This maneuver decreases the intravascular volume and improves inflow thereby allowing Korotkoff sounds to be heard.[13]

Ambulatory and Self-BP Monitoring Ambulatory BP (ABP) monitoring using an automated device can document BP at frequent time intervals (e.g., every 15 to 30 minutes) throughout a 24-hour period.[13] ABP values are usually lower than clinic-measured values. The upper limit for normal ABP is 140/90 mm Hg during the day, 125/75 mm Hg at night, and 135/85 mm Hg during 24 hours. Self-BP measurements are collected by patients, preferably in the morning, using home monitoring devices.

Neither ABP nor self-BP monitoring are needed for the routine diagnosis of hypertension; however, these modalities can enhance the ability to identify patients with white coat and masked hypertension.[14] ABP and self-BP measurements may also be useful in evaluating BP control for patients on antihypertensive drug therapy.[14] ABP monitoring may be helpful for patients with apparent drug resistance, hypotensive symptoms while on antihypertensive therapy, episodic hypertension (e.g., white coat hypertension), and autonomic dysfunction and in identifying "non-dippers" whose BP does not decrease by >10% during sleep and who may portend increased risk of BP-related complications.[1,13]

Limitations of ABP and self-BP measurements may prohibit routine use of such technology. These include complexity of use, costs, and lack of prospective outcome data describing normal ranges for these measurements. Although self-monitoring of BP at home is less complicated and less costly than ambulatory monitoring, patients may omit or fabricate readings.

CLINICAL EVALUATION

Frequently, the only sign of essential hypertension is elevated BP. The rest of the physical examination may be completely normal. However, a complete medical evaluation (a comprehensive medical history, physical examination, and laboratory and/or diagnostic tests) is recommended after diagnosis to (1) identify secondary causes, (2) identify other CV risk factors or comorbid conditions that may define prognosis and/or guide therapy, and (3) assess for the presence or absence of hypertension-associated target-organ damage.[1] All patients with hypertension should have the tests described in Box 19–1 measured prior to initiating therapy.[1] For patients without a history of coronary artery disease, noncoronary atherosclerotic vascular disease, left ventricular dysfunction, or diabetes it is also important to estimate a 10-year risk of fatal coronary heart disease or nonfatal MI using Framingham risk scoring. (*http://www.nhlbi.nih.gov/guidelines/cholesterol/risk_tbl.htm*).[2]

Secondary Causes

The most common secondary causes of hypertension are listed in Table 19–1. A complete medical evaluation should provide clues for identifying secondary hypertension.

Patients with secondary hypertension might have signs or symptoms suggestive of the underlying disorder. Patients with pheochromocytoma may have a history of paroxysmal headaches, sweating, tachycardia, and palpitations. Over half of these patients suffer from episodes of orthostatic hypotension. In primary hyperaldosteronism symptoms related to hypokalemia usually include muscle cramps and muscle weakness. Patients with Cushing syndrome may complain of weight gain, polyuria, edema, menstrual irregularities, recurrent acne, or muscular weakness and have several classic physical features (e.g., moon face, buffalo hump, hirsutism). Patients with coarctation of the aorta may have higher BP in the arms than legs and diminished or even absent femoral pulses. Patients with renal artery stenosis may have an abdominal systolic-diastolic bruit.

Routine laboratory tests may also help identify secondary hypertension. Baseline hypokalemia may suggest mineralocorticoid-induced hypertension. Protein, red blood cells, and casts in the urine may indicate renovascular disease. Some laboratory tests are used specifically to diagnose secondary hypertension. These include plasma norepinephrine and urinary metanephrine for pheochromocytoma, plasma and urinary aldosterone concentrations for primary hyperaldosteronism, plasma renin activity, captopril stimulation test, renal vein renin, and renal artery angiography for renovascular disease.

Certain drugs and other products can result in drug-induced hypertension (see Table 19–1). For some patients, the addition of these agents can be the cause of hypertension or can exacerbate underlying hypertension. Identifying a temporal relationship between starting the suspected agent and developing elevated BP is most suggestive of drug-induced BP elevation.

NATURAL COURSE OF DISEASE

Essential hypertension is usually preceded by elevated BP values that are in the prehypertension category. BP values may fluctuate between elevated and normal levels for an extended period of time. During this stage, many patients have a hyperdynamic circulation with increased CO and normal or even low peripheral vascular resistance. As the disease progresses, peripheral vascular resistance increases, and BP elevation becomes chronic.

Hypertension-Associated Target-Organ Damage

Target-organ damage (see Box 19–1) can develop as a complication of hypertension. CV events (e.g., MI, cerebrovascular accidents, kidney failure) are clinical end points of hypertension-associated target-organ damage and are the primary causes of CV morbidity and mortality for patients with hypertension. The probability of CV events and CV morbidity and mortality in patients with hypertension is directly correlated with the severity of BP elevation.

Hypertension accelerates atherosclerosis and stimulates left ventricular and vascular dysfunction. These pathologic changes are thought to be secondary to both a chronic pressure overload and a variety of nonhemodynamic stimuli. Several nonhemodynamic disturbances have been implicated in these effects (e.g., the adrenergic system, RAAS, increased synthesis and secretion of endothelin I, and a decreased production of prostacyclin and nitric oxide). Atherosclerosis in hypertension is accompanied by proliferation of smooth muscle cells, lipid infiltration into the vascular endothelium, and an enhancement of vascular calcium accumulation.

Cerebrovascular disease is a consequence of hypertension. A neurologic assessment can detect either gross neurologic deficits or a slight hemiparesis with some incoordination and hyperreflexia that are indicative of cerebrovascular disease. Stroke can result from lacunar infarcts caused by thrombotic occlusion of small vessels or intracerebral hemorrhage resulting from ruptured microaneurysms. Transient ischemic attacks secondary to atherosclerotic disease in the carotid arteries are common for patients with hypertension.

Retinopathies can occur in hypertension and may manifest as a variety of different findings. A funduscopic examination can detect hypertensive retinopathy, and the result can be categorized according to the Keith-Wagener-Barker retinopathy classification. Retinopathy manifests as arteriolar narrowing, focal arteriolar constrictions, arteriovenous crossing changes (nicking), retinal hemorrhages and exudates, and disk edema. Accelerated arteriosclerosis, a long-term consequence of essential hypertension, can cause nonspecific changes such as increased light reflex, increased tortuosity of vessels, and arteriovenous nicking. Focal arteriolar narrowing, retinal infarcts, and flame-shaped hemorrhages usually are suggestive of accelerated or malignant phase of hypertension. Papilledema is swelling of the optic disk caused by a breakdown in autoregulation of capillary blood flow in the presence of high pressure. It is usually only present in hypertensive emergencies.

Heart disease is the most well-identified form of target-organ damage. A thorough cardiac and pulmonary examination can identify cardiopulmonary abnormalities. Clinical manifestations include left ventricular hypertrophy, coronary heart disease (angina, prior MI, and prior coronary revascularization), and heart failure. These complications may lead to cardiac arrhythmias, angina, MI, and sudden death. Coronary disease (also called *coronary heart disease*) and associated CV events are the most common causes of death in patients with hypertension.

The kidney damage caused by hypertension is characterized pathologically by hyaline arteriosclerosis, hyperplastic arteriosclerosis, arteriolar hypertrophy, fibrinoid necrosis, and atheroma of the major renal arteries. Glomerular hyperfiltration and intraglomerular hypertension are early stages of hypertensive nephropathy. Microalbuminuria is followed by a gradual decline in renal function. The primary renal complication in hypertension is nephrosclerosis, which is secondary to arteriosclerosis. Atheromatous disease of a major renal artery may give rise to renal artery stenosis. Although overt kidney failure is an uncommon complication of essential hypertension, it is an important cause of end-stage kidney disease, especially in African-Americans, Hispanics, and Native Americans.

The peripheral vasculature is a target organ. Physical examination of the vascular system can detect evidence of atherosclerosis, which may present as arterial bruits (aortic, abdominal, or peripheral), distended veins, diminished or absent peripheral arterial pulses, or lower extremity edema. Peripheral arterial disease is a clinical condition that can result from atherosclerosis, which is accelerated in hypertension. Other CV risk factors (e.g., smoking) can increase the likelihood of peripheral arterial disease as well as all other forms of target-organ damage.

TREATMENT

DESIRED OUTCOMES

Overall Goal of Treatment

4 The overall goal of treating hypertension is to reduce hypertension-associated morbidity and mortality.[1] This morbidity and mortality is related to hypertension-associated target-organ damage (e.g., CV events, cerebrovascular events, heart failure, kidney disease). Reducing CV risk remains the primary purpose of hypertension therapy and the specific choice of drug therapy is significantly influenced by evidence demonstrating such CV risk reduction.

Surrogate Targets—Blood Pressure Goals

5 Treating patients with hypertension to achieve a desired target BP value is simply a surrogate goal of therapy. Reducing BP to goal does not guarantee prevention of hypertension-associated target-organ

damage, but is associated with a lower risk of hypertension-associated target-organ damage.[1] Targeting a goal BP value is a tool that clinicians use to evaluate response to therapy. It is the primary method used to determine the need for titration and regimen modification.

The JNC7 and AHA 2007 guidelines each recommend BP goals (Box 19–2) for the management of hypertension. Both guidelines recommend a goal BP of less than 140/90 mm Hg for most patients for the general prevention of CV events or CV disease (e.g., coronary artery disease).[1,2] A lower BP goal of less than 130/80 mm Hg is recommended by both of these guidelines for patients with diabetes or significant chronic kidney disease, although data supporting that this goal provides better reductions in CV events than less than 140/90 mm Hg is not definitive.[1,2] Moreover, the AHA 2007 guidelines also recommend the goal of less than 130/80 mm Hg for patients with known coronary artery disease (MI, stable angina, unstable angina), noncoronary atherosclerotic vascular disease (ischemic stroke, transient ischemic attack, peripheral arterial disease, abdominal aortic aneurysm) or a 10% or greater 10-year risk of fatal coronary heart disease or non-fatal MI based on Framingham risk scoring (*http://www.nhlbi.nih.gov/guidelines/cholesterol/risk_tbl.htm*).[2] The AHA 2007 guidelines also recommend BP goal of less than 120/80 mm Hg for patients with left ventricular dysfunction (heart failure).[2] Similar to diabetes or chronic kidney disease, data supporting that these lower BP goal provides better reductions in CV events than less than 140/90 mm Hg are not definitive.

The BP goals recommended by the JNC7 should be considered standard, or minimum, BP goals. The expanded, lower BP goals recommended by the AHA 2007 guidelines for patients with known coronary artery disease, noncoronary atherosclerotic vascular disease, a Framingham risk score of 10% or greater, or left ventricular dysfunction should be considered optional goals for more aggressive management of hypertension. The determination of which approach to follow has been widely debated.[16] Definitive evidence proving that the lower optional BP goals recommended by the AHA reduce risk of hypertension-associated target organ damage greater than the standard JNC7 goals is not available. When available, the BP goals recommended in the JNC8 will represent the most updated expert consensus. Until that time, clinicians should at minimum target the JNC7 BP goals, and then target the extended, more aggressive AHA 2007 guideline BP goals based on clinical judgment.

BOX 19-2 GOAL BP VALUES RECOMMENDED BY THE JNC 7 IN 2003[1] AND AHA IN 2007[2]

	JNC7	AHA
Most Patients for General Prevention:	<140/90 mm Hg	<140/90 mm Hg
Patients with ▪ Diabetes ▪ Significant chronic kidney disease	<130/80 mm Hg	<130/80 mm Hg
Patients with ▪ Known coronary artery disease (MI, stable angina, unstable angina) ▪ Noncoronary atherosclerotic vascular disease (ischemic stroke, transient ischemic attack, peripheral arterial disease, abdominal aortic aneurysm) ▪ Framingham risk score of 10% or greater	No specific recommendation	<130/80 mm Hg
Patients with left ventricular dysfunction (heart failure)	No specific recommendation	120/80 mm Hg

Significant chronic kidney disease is considered to be moderate-to-severe chronic kidney disease, defined as estimated glomerular filtration rate (GFR) <60 mL/minute/1.73 m^2 (correlating to a serum creatinine >1.3 mg/dL in women or >1.5 in men); or albuminuria (>300 mg/day or >200 mg/g creatinine).

Framingham risk score calculated using the risk calculator available at *http://www.nhlbi.nih.gov/guidelines/cholesterol/risk_tbl.htm*

Evidence Supporting <140/90 mm Hg in Most Patients Lower goal DBP values have been evaluated prospectively in the Hypertension Optimal Treatment (HOT) study.[17] In this study, over 18,700 patients were randomized to target DBP values of ≤90 mm Hg, ≤85 mm Hg, ≤ or 80 mm Hg. Although the actual DBP values achieved were 85.2, 83.2, and 81.1 mm Hg, respectively, there were no significant differences in risk of major CV events when the three treatment groups were compared to each other among the total population. This lack of a benefit in reducing risk of CV events is consistent with findings from a 2009 Cochrane Collaboration systematic review that included 7 clinical trials which evaluated different goal DBP values in hypertension.[18] When the relationship between actual BP values and risk of CV events was evaluated there was trend that lower was better. The risk of major CV events was the lowest with a BP of 139/83 mm Hg, and lowest risk of stroke was with a BP of 142/80 mm Hg.

A major limitation of the HOT study and the 2009 Cochrane Collaboration review is the use of DBP goal values. SBP is more directly correlated to CV risk than DBP in most patients with hypertension, especially those above the age of 50. Therefore, data from the HOT study can not answer this question. It is important to note that no J-curve relationship was seen. The *J-curve hypothesis* suggests that lowering BP too much might increase the risk of CV events.[19] This theoretical hypothesis was described many years ago and was originally suggested in observational studies. Therefore, it remains an unproven hypothesis.

Limited data suggests lower is better when SBP goal values are targeted. The Cardio-Sys trial was a small open-label study in 1,111 patients with hypertension and without a history of diabetes.[20] These patients had additional CV risk factors and roughly reflect a population with a Framingham risk score of 10% or greater. Patients were randomized to SBP goals of less than 140 mm Hg or less than 130 mm Hg. After a median of 2 years, the incidence of left ventricular hypertrophy was lower in the group randomized to a SBP goal of less than 130 mm Hg. Interestingly, the incidence of CV events, which was a secondary end point, was also significantly lower in the less than 130 mm Hg group. These data suggest that the optional lower BP goals may be better. Left ventricular hypertrophy is only a surrogate end point for CV events, and the open-label nature of this study limits broad application to patient care.

CLINICAL CONTROVERSY

How low to go in most patients?

A standard BP goal of less than 140/90 mm Hg is recommended by both the JNC7 and AHA guidelines for most patients, while less than 130/80 mm Hg is recommended in other higher risk patient populations (e.g., diabetes, significant chronic kidney disease, coronary artery disease, ischemic stroke).[1,2] However, some clinicians believe that lower BP goals are better, even for

patients that do not have one of the aforementioned higher risk conditions. One ongoing trial that is sponsored by National Heart, Lung, and Blood Institute (NHLBI), the Systolic Pressure Intervention Trial (SPRINT), is a prospective randomized trial that is evaluating standard BP goals with lower BP goals for patients without a history of diabetes or a history of stroke. Once this trial is completed, hopefully the controversy of how low to go in most patients will be resolved.

Evidence Supporting <130/80 mm Hg in Diabetes A BP goal of <130/80 mm Hg has been recommended for patients with diabetes for many years, by multiple organizations.[1,2,21,22] The primary evidence supporting this recommendation was from the HOT study, where the only subgroup to show a lower risk of major CV events in the less than 80 mm Hg group versus the less than 90 mm Hg group was in patient with diabetes (n = 1,501). There was a trend that lower was better in the 3,080 patients with ischemic heart disease [e.g., previous MI, other forms of coronary heart disease (CHD)], but this failed to meet statistical significance.

In 2010, results of the NHLBI-sponsored Action to Control Cardiovascular Risk in Diabetes Blood Pressure (ACCORD-BP) study further questioned the benefit of lower BP goals for patients with diabetes.[23] The ACCORD-BP was an open-label study that randomized 4,733 patients with type 2 diabetes to intensive therapy targeting a SBP of less than 120 mm Hg, or to standard therapy to targeting a SBP less than 140 mm Hg for a mean follow up of 4.7 years. After 1 year, a mean number of medications of 3.4 was needed in the intensive therapy group to attain a mean SBP of 119.3 mm Hg, compared with a mean number of medications of 2.1 in the standard therapy group to attain a mean SBP of 133.5 mm Hg. This difference was generally maintained throughout the study duration. However, there was no significant difference in the annual rate of the primary end point (nonfatal MI, nonfatal stroke, or CV death) between the two groups. The annual incidence of the secondary end point of stroke was lower with the intensive therapy group versus the standard therapy group, and this was the only prespecified end point that was different between the two groups.

Despite consensus guidelines recommending a BP goal of less than 130/80 mm Hg for patients with diabetes, evidence supporting this approach over a standard goal of less than 140/90 mm Hg is marginal. If there are additional clinical benefits of this lower BP goal, they may be limited to certain types of CV events (e.g., stroke). While the ACCORD-BP provided additional evidence regarding BP goals for patients with diabetes, these data do not provide all of the clinical answers that are needed. The ACCORD-BP was open-label, and those in the standard group (SBP less than 140 mm Hg) actually had SBP values that were closer to 130 mm Hg than 140 mm Hg. Clinicians should acknowledge that the best available evidence suggests that a BP goal of less than 130/80 mm Hg is possibly only marginally better than a standard goal BP of less than 140/90 mm Hg for patients with diabetes.

AVOIDING CLINICAL INERTIA

Although hypertension is one of the most common medical conditions, BP control rates are poor. *Clinical inertia* in hypertension has been defined as an office visit at which no therapeutic move was made to lower BP in a patient with uncontrolled hypertension.[24] Clinical inertia is not the entire reason why many patients with hypertension do not achieve goal BP values. However, it is certainly a major reason that can be remedied simply through more aggressive treatment with drug therapy. This can involve initiating, titrating, or changing drug therapy.

GENERAL APPROACH TO TREATMENT

After a diagnosis of hypertension is made, most patients should be placed on both lifestyle modifications and drug therapy concurrently. Lifestyle modification alone is appropriate therapy for most patients with prehypertension. However, lifestyle modifications alone are not considered adequate for patients with hypertension and additional CV risk factors or hypertension-associated target organ damage.

6 The choice of initial drug therapy depends on the degree of BP elevation and presence of compelling indications (discussed in the Pharmacotherapy section). Most patients with stage 1 hypertension should be initially treated with a first-line antihypertensive drug, or the combination of two agents. Combination drug therapy is recommended for patients with more severe BP elevation (stage 2 hypertension), using preferably two first-line antihypertensive drugs. This general approach is outlined in Figure 19–2. There are six compelling indications where specific

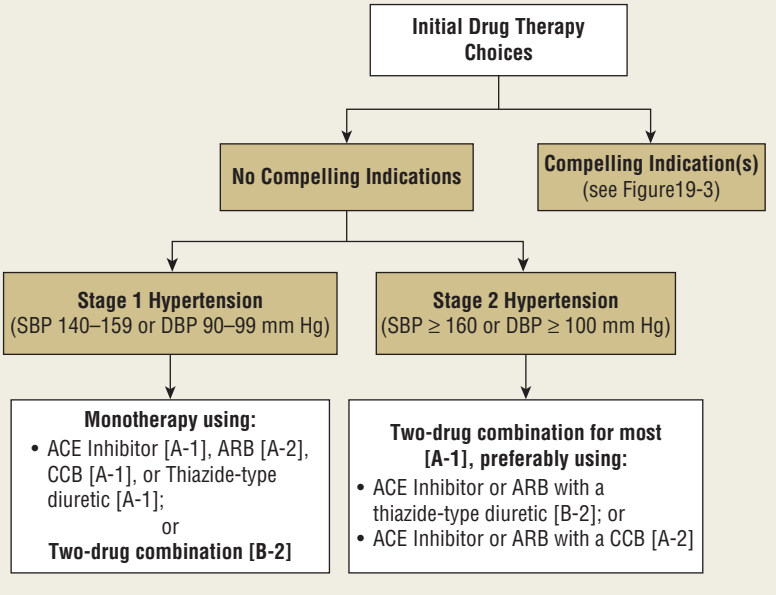

FIGURE 19-2. Algorithm for treatment of hypertension. Drug therapy recommendations are graded with strength of recommendation and quality of evidence in brackets. Strength of recommendations: A, B, and C are good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: (1) Evidence from more than 1 properly randomized, controlled trial. (2) Evidence from at least one well-designed clinical trial with randomization, from cohort or case-controlled studies, or dramatic results from uncontrolled experiments or subgroup analyses. (3) Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities. *(Adapted from the JNC7 and the AHA.[1,2])*

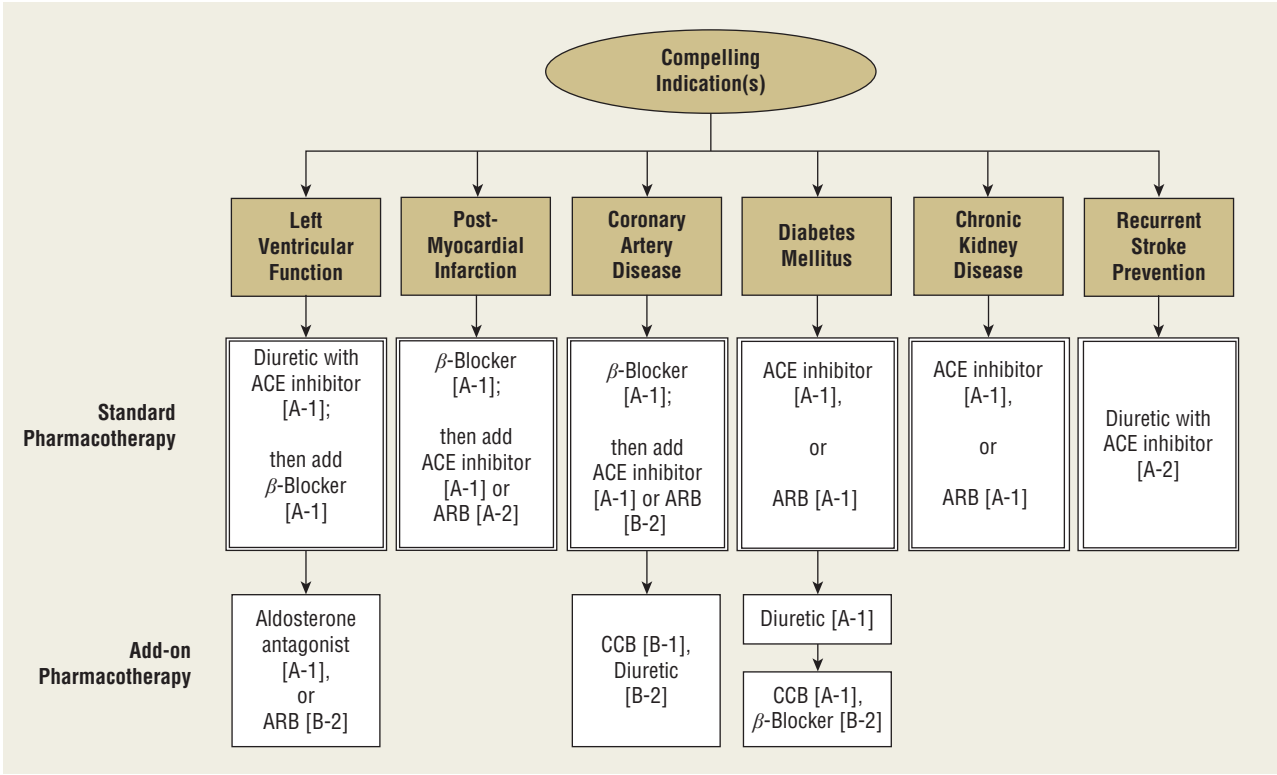

FIGURE 19-3. Compelling indications for individual drug classes (adapted from the JNC7,[1] AHA,[2] and other evidence[58]). Compelling indications for specific drugs are evidenced-based recommendations from outcome studies or existing clinical guidelines. The order of drug therapies serves as a general guidance that should be balanced with clinical judgment and patient response; however, standard pharmacotherapy should be considered first-line recommendations, preferably in the order depicted. Then add-on pharmacotherapy recommendations are intended to further reduce risk of cardiovascular events when additional pharmacotherapy is needed to lower blood pressure to goal values. Blood pressure control should be managed concurrently with the compelling indication. Drug therapy recommendations are graded with strength of recommendation and quality of evidence in brackets. Strength of recommendations: A, B, and, C are good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: (1) Evidence from more than one properly randomized, controlled trial. (2) Evidence from at least one well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series, or dramatic results from uncontrolled experiments or subgroup analyses. (3) Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

antihypertensive drug classes have evidence showing unique benefits in patients with hypertension and the listed compelling indication (Fig. 19–3).

NONPHARMACOLOGIC THERAPY

7 All patients with prehypertension and hypertension should be prescribed lifestyle modifications. Recommended modifications that have been shown to lower BP are listed in Table 19–4.[1,25] They can provide small to moderate reductions in SBP. Aside from lowering BP in patients with known hypertension, lifestyle modification can decrease the progression to hypertension in patients with prehypertension BP values.[25]

A sensible dietary program is one that is designed to reduce weight gradually (for overweight and obese patients) and one that restricts sodium intake with only moderate alcohol consumption. Successful implementation of dietary lifestyle modifications by clinicians requires aggressive promotion through reasonable patient

TABLE 19-4 Lifestyle Modifications to Prevent and Manage Hypertension

Modification	Recommendation	Approximate Systolic Blood Pressure Reduction (mm Hg)[a]
Weight loss	Maintain normal body weight (body mass index, 18.5–24.9 kg/m^2)	5–20 per 10-kg weight loss
DASH-type dietary patterns	Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat	8–14
Reduced salt intake	Reduce daily dietary sodium intake as much as possible, ideally to ≈65 mmol/day (1.5 g/day sodium, or 3.8 g/day sodium chloride)	2–8
Physical activity	Regular aerobic physical activity (at least 30 minutes/day, most days of the week)	4–9
Moderation of alcohol intake	Limit consumption to less than or equal to 2 drink equivalents per day in men and less than or equal to 1 drink equivalent per day in women and lighter weight persons[b]	2–4

[a]Effects of implementing these modifications are time- and dose-dependent and could be greater for some patients.
[b]One drink equivalent is equal to 1.5 oz of 80-proof distilled spirits (e.g., whiskey), a 5 oz glass of wine (12%), or 12 oz of beer.
Data from references (1, 24)

education, encouragement, and continued reinforcement. Patients may better understand the rationale for dietary intervention in hypertension if they are provided the following three observations and facts:[25]

1. Weight loss, as little as 10 lb, can decrease BP significantly in overweight patients.
2. Diets rich in fruits and vegetables and low in saturated fat have been shown to lower BP in patients with hypertension.
3. Most people experience some degree of SBP reduction with sodium restriction.

The Dietary Approaches to Stop Hypertension (DASH) eating plan is a diet that is rich in fruits, vegetables and low-fat dairy products with a reduced content of saturated and total fat. It is advocated by the JNC7 as a reasonable and feasible diet that is proven to lower BP. Intake of sodium should be minimized as much as possible, ideally to 1.5 g/day, though an interim goal of less than 2.3 g/day may be reasonable considering the difficulty in achieving these low intakes. Patients should be aware of the multiple sources of dietary sodium (e.g., processed foods, soups, table salt) so that they may follow these recommendations. Potassium intake should be encouraged through fruits and vegetables with high content (ideally 4.7 g/day) in those with normal kidney function or without impaired potassium excretion. Excessive alcohol use can either cause or worsen hypertension. Patients with hypertension who drink alcoholic beverages should restrict their daily intake.

Carefully designed programs of physical activity can lower BP. Regular physical activity for at least 30 minutes most days of the week is recommended for all adults, with at least 60 minutes recommended for adults attempting to lose weight or maintain weight loss.[26] Studies have shown that aerobic exercise can reduce BP, even in the absence of weight loss. Patients should consult their physicians before starting an exercise program, especially those with CV and/or hypertension-associated target-organ disease.

Cigarette smoking, while not considered a secondary cause of essential hypertension, is a major, independent, modifiable risk factor for CV disease. Patients with hypertension who smoke should be counseled regarding the additional health risks that result from smoking. Moreover, the potential benefits that cessation can provide should be explained to encourage cessation.

PHARMACOTHERAPY

8 A thiazide-type diuretic, ACE inhibitor, angiotensin II receptor blocker (ARB), or calcium channel blocker (CCB) are considered primary antihypertensive agents that are acceptable first-line options (Table 19–5). These agents should be used to treat the majority of

TABLE 19-5 Primary Antihypertensive Agents

Class	Subclass	Drug (Brand Name)	Usual Dose Range, mg/day	Daily Frequency	Comments
Diuretics	Thiazides	Chlorthalidone (Hygroton)	6.25–25	1	Dose in the morning to avoid nocturnal diuresis; thiazides are more effective antihypertensives than loop diuretics in most patients; use usual doses to avoid adverse metabolic effects; hydrochlorothiazide and chlorthalidone are preferred; chlorthalidone is approximately 1.5 times as potent as hydrochlorothiazide; have additional benefits in osteoporosis; may require additional monitoring in patients with a history of gout or hyponatremia
		Hydrochlorothiazide (Esidrix, HydroDiuril, Microzide, Oretic)	12.5–25	1	
		Indapamide (Lozol)	1.25–2.5	1	
		Metolazone (Mykrox)	0.5–1	1	
		Metolazone (Zaroxolyn)	2.5–10	1	
	Loops	Bumetanide (Bumex)	0.5–4	2	Dose in the morning and late afternoon (when twice daily) to avoid nocturnal diuresis; higher doses may be needed for patients with severely decreased glomerular filtration rate or heart failure
		Furosemide (Lasix)	20–80	2	
		Torsemide (Demadex)	5–10	1	
	Potassium sparing	Amiloride (Midamor)	5–10	1 or 2	Dose in the morning and late afternoon (when twice daily) to avoid nocturnal diuresis; weak diuretics that are generally used in combination with thiazide-type diuretics to minimize hypokalemia; do not significantly lower BP unless used with a thiazide-type diuretic; should generally be reserved for patients experiencing diuretic-induced hypokalemia; avoid in patients with chronic kidney disease (estimated creatinine clearance <30 mL/min); may cause hyperkalemia, especially in combination with an ACE inhibitor, ARB, direct renin inhibitor, or potassium supplements
		Amiloride/hydrochlorothiazide (Moduretic)	5–10/50–100	1	
		Triamterene (Dyrenium)	50–100	1 or 2	
		Triamterene/hydrochlorothiazide (Dyazide)	37.5–75/25–50	1	
	Aldosterone Antagonists	Eplerenone (Inspra)	50–100	1 or 2	Dose in the morning and late afternoon (when twice daily) to avoid nocturnal diuresis; eplerenone contraindicated in patients with an estimated creatinine clearance <50 mL/min, elevated serum creatinine (>1.8 mg/dL in women, >2 mg/dL in men), and type 2 diabetes with microalbuminuria; sprionolactone often used as add-on therapy in resistant hypertension; avoid spironolactone in patients with chronic kidney disease (estimated creatinine clearance <30 mL/min); may cause hyperkalemia, especially in combination with an ACE inhibitor, ARB, direct renin inhibitor or potassium supplements
		Spironolactone (Aldactone)	25–50	1 or 2	
		Spironolactone/hydrochlorothiazide (Aldactazide)	25–50/25–50	1	

(continued)

TABLE 19-5 Primary Antihypertensive Agents (continued)

Class	Subclass	Drug (Brand Name)	Usual Dose Range, mg/day	Daily Frequency	Comments
ACE inhibitors		Benazepril (Lotensin)	10–40	1 or 2	May cause hyperkalemia in patients with chronic kidney disease or in those receiving potassium-sparing diuretic, aldosterone antagonist, ARB, or direct renin inhibitor; can cause acute kidney failure in patients with severe bilateral renal artery stenosis or severe stenosis in artery to solitary kidney; do not use in pregnancy or in patients with a history of angioedema; starting dose should be reduced 50% in patients who are on a diuretic, are volume depleted, or are very elderly due to risks of hypotension.
		Captopril (Capoten)	12.5–150	2 or 3	
		Enalapril (Vasotec)	5–40	1 or 2	
		Fosinopril (Monopril)	10–40	1	
		Lisinopril (Prinivil, Zestril)	10–40	1	
		Moexipril (Univasc)	7.5–30	1 or 2	
		Perindopril (Aceon)	4–16	1	
		Quinapril (Accupril)	10–80	1 or 2	
		Ramipril (Altace)	2.5–10	1 or 2	
		Trandolapril (Mavik)	1–4	1	
ARBs		Candesartan (Atacand)	8–32	1 or 2	May cause hyperkalemia in patients with chronic kidney disease or in those receiving potassium-sparing diuretic, aldosterone antagonist, ACE inhibitor, or direct renin inhibitor; can cause acute kidney failure in patients with severe bilateral renal artery stenosis or severe stenosis in artery to solitary kidney; do not cause a dry cough like ACE inhibitors may; do not use in pregnancy; starting dose should be reduced 50% in patients who are on a diuretic, are volume depleted, or are very elderly due to risks of hypotension.
		Eprosartan (Teveten)	600–800	1 or 2	
		Irbesartan (Avapro)	150–300	1	
		Losartan (Cozaar)	50–100	1 or 2	
		Olmesartan (Benicar)	20–40	1	
		Telmisartan (Micardis)	20–80	1	
		Valsartan (Diovan)	80–320	1	
Calcium channel blockers	Dihydropyridines	Amlodipine (Norvasc)	2.5–10	1	Short-acting dihydropyridines should be avoided, especially immediate-release nifedipine and nicardipine; dihydropyridines are more potent peripheral vasodilators than nondihydropyridines and may cause more reflex sympathetic discharge (tachycardia), dizziness, headache, flushing, and peripheral edema; have additional benefits in Raynaud's syndrome
		Felodipine (Plendil)	5–20	1	
		Isradipine (DynaCirc)	5–10	2	
		Isradipine SR (DynaCirc SR)	5–20	1	
		Nicardipine sustained release (Cardene SR)	60–120	2	
		Nifedipine long-acting (Adalat CC, Nifedical XL, Procardia XL)	30–90	1	
		Nisoldipine (Sular)	10–40	1	
	Non-dihydropyridines	Diltiazem sustained-release (Cardizem SR)	180–360	2	Extended-release products are preferred for hypertension; these agents reduce heart rate; may produce heart block, especially in combination with β-blockers; these products are not AB rated as interchangeable on a equipotent mg-per-mg basis due to different release mechanisms and different bioavailability parameters; Cardizem LA, Covera HS, and Verelan PM have delayed drug release for several hours after dosing, when dosed in the evening can provide chronotherapeutic drug delivery starting shortly before patients awake from sleep; non-dihydropyridines have additional benefits in patients with atrial tachyarrhythmia
		Diltiazem sustained-release (Cardizem CD, Cartia XT, Dilacor XR, Diltia XT, Tiazac, Taztia XT)	120–480	1	
		Diltiazem extended-release (Cardizem LA)	120–540	1 (morning or evening)	
		Verapamil sustained-release (Calan SR, Isoptin SR, Verelan)	180–480	1 or 2	
		Verapamil controlled-onset extended-release (Covera HS)	180–420	1 (in the evening)	
		Verapamil chronotherapeutic oral drug absorption system (Verelan PM)	100–400	1 (in the evening)	
β-blockers	Cardioselective	Atenolol (Tenormin)	25–100	1	Abrupt discontinuation may cause rebound hypertension; inhibit β_1 receptors at low to moderate dose, higher doses also block β_2 receptors; may exacerbate asthma when selectivity is lost; have additional benefits in patients with atrial tachyarrhythmia or preoperative hypertension
		Betaxolol (Kerlone)	5–20	1	
		Bisoprolol (Zebeta)	2.5–10	1	
		Metoprolol tartrate (Lopressor)	100–400	2	
		Metoprolol succinate extended release (Toprol XL)	50–200	1	
	Nonselective	Nadolol (Corgard)	40–120	1	Abrupt discontinuation may cause rebound hypertension; inhibit β_1 and β_2 receptors at all doses; can exacerbate asthma; have additional benefits in patients with essential tremor, migraine headache, thyrotoxicosis
		Propranolol (Inderal)	160–480	2	
		Propranolol long-acting (Inderal LA, InnoPran XL)	80–320	1	
		Timolol (Blocadren)	10–40	1	

(continued)

TABLE 19-5 Primary Antihypertensive Agents (continued)

Class	Subclass	Drug (Brand Name)	Usual Dose Range, mg/day	Daily Frequency	Comments
	Intrinsic sympathomimetic activity	Acebutolol (Sectral)	200–800	2	Abrupt discontinuation may cause rebound hypertension; partially stimulate β-receptors while blocking against additional stimulation; no clear advantage for these agents; contraindicated in patients post-myocardial infarction
		Carteolol (Cartrol)	2.5–10	1	
		Penbutolol (Levatol)	10–40	1	
		Pindolol (Visken)	10–60	2	
	Mixed α- and β-blockers	Carvedilol (Coreg)	12.5–50	2	Abrupt discontinuation may cause rebound hypertension; additional α blockade produces vasodilation and more orthostatic hypotension
		Carvedilol phosphate (Coreg CR)	20–80	1	
		Labetalol (Normodyne, Trandate)	200–800	2	
	Cardioselective and vasodilatory	Nebivolol (Bystolic)	5–20	1	Abrupt discontinuation may cause rebound hypertension; additional vasodilation does not result in more orthostatic hypotension

patients with hypertension because evidence from outcome data has demonstrated CV risk-reduction benefits with these classes. Several have subclasses where significant differences in mechanism of action, clinical use, side effects, or evidence from outcome studies exist. β-blockers are effective antihypertensive agents that previously were considered primary agents. They are now preferred either to treat a specific compelling indication, or in combination with one or more of the aforementioned primary antihypertensive agents for patients without a compelling indication. Other antihypertensive drug classes are considered alternative drug classes that may be used in select patients after first-line agents (Table 19–6).

Thiazide-Type Diuretics as First-Line Agents

JNC7 guidelines (from 2003) recommend thiazide-type diuretics whenever possible, as first-line therapy for most patients, and is consistent with the traditional pharmacotherapy of hypertension.[1] However, the AHA 2007 guidelines do not identify thiazide-type diuretics as preferred over an ACE inhibitor, ARB, or CCB for first-line therapy. Figure 19–2 displays the algorithm for the treatment of hypertension. This recommendation is specifically for patients without compelling indications and is based on best available evidence demonstrating reductions in CV morbidity and mortality.

Landmark placebo-controlled clinical trials demonstrate that thiazide-type diuretic therapy irrefutably reduces risk of CV morbidity and mortality.[27] The Systolic Hypertension in the Elderly Program (SHEP),[8] Swedish Trial in Old Patients with Hypertension (STOP-Hypertension),[9] and Medical Research Council (MRC)[10] studies showed significant reductions in stroke, MI, all cause CV disease, and mortality with thiazide-type diuretic-based therapy versus placebo. These trials allowed for β-blockers as add on therapy for BP control. Newer agents (ACE inhibitors, ARBs, and CCBs) were not available at the time of these studies. However, subsequent clinical trials have compared these newer antihypertensive agents to thiazide-type diuretics.[28–33] These data show similar effects, but most trials used a prospective open-label, blinded end point (PROBE) study methodology that is not double-blinded and limited their ability to prove equivalence of newer drugs to diuretics. Other prospective trials have compared different primary antihypertensive agents to each other.[30,34,35] Although these studies used head-to-head comparisons, they did not use a thiazide-type diuretic as their comparator treatment.

The Antihypertensive and Lipid Lowering Treatment to Prevent Heart Attack Trial (ALLHAT)[31] The results of the ALLHAT was the deciding evidence that the JNC7 used to justify thiazide-type diuretics as first-line therapy.[31] It was designed to test the hypothesis that newer antihypertensive agents (an α-blocker, ACE inhibitor, or dihydropyridine CCB) would be superior to thiazide-type diuretic-based therapy. The primary objective was to compare the combined end point of fatal CHD and nonfatal MI. Other hypertension-related complications (e.g., heart failure, stroke)

TABLE 19-6 Alternative Antihypertensive Agents

Class	Drug (Brand Name)	Usual Dose Range in mg/day	Daily Frequency	Comments
α_1-Blockers	Doxazosin (Cardura)	1–8	1	Give first dose at bedtime; patients should rise from sitting or laying down slowly to minimize risk of orthostatic hypotension; additional benefits in men with benign prostatic hyperplasia
	Prazosin (Minipress)	2–20	2 or 3	
	Terazosin (Hytrin)	1–20	1 or 2	
Direct renin inhbitor	Aliskiren (Tekturna)	150–300	1	May cause hyperkalemia in patients with chronic kidney disease and diabetes or in those receiving a potassium-sparing diuretic, aldosterone antagonist, ACE inhibitor, or ARB; may cause acute kidney failure in patients with severe bilateral renal artery stenosis or severe stenosis in artery to solitary kidney; do not use in pregnancy
Central α_2-agonists	Clonidine (Catapress)	0.1–0.8	2	Abrupt discontinuation may cause rebound hypertension; most effective if used with a diuretic to diminish fluid retention; clonidine patch is replaced once per week
	Clonidine patch (Catapress- TTS)	0.1–0.3	1 weekly	
	Methyldopa (Aldomet)	250–1000	2	
Peripheral adrenergic antagonist	Reserpine (generic only)	0.05–0.25		Used in many of the landmark clinical trials; should be used with a diuretic to diminish fluid retention
Direct arterial vasodilators	Minoxidil (Loniten)	10–40	1 or 2	Should be used with diuretic and β-blocker to diminish fluid retention and reflex tachycardia
	Hydralazine (Apresoline)	20–100	2 to 4	

were evaluated as secondary end points. This was the largest prospective hypertension trial ever conducted and included 42,418 patients age 55 and older with hypertension and one additional CV risk factor. This double-blind trial randomized patients to chlorthalidone, amlodipine, doxazosin, or lisinopril-based therapy for a mean of 4.9 years.

The doxazosin arm was terminated early when a significantly higher risk of heart failure versus chlorthalidone was observed.[36] The other arms were continued as scheduled and no significant differences in the primary end point were seen between the chlorthalidone and lisinopril or amlodipine treatment groups. However, chlorthalidone had statistically fewer secondary end points than amlodipine (heart failure) and lisinopril (combined CV disease, heart failure, and stroke). The study conclusions were that chlorthalidone-based therapy was superior in preventing one or more major forms of CV disease and was less expensive than amlodipine or lisinopril-based therapy.

ALLHAT was designed as a superiority study with the hypothesis that amlodipine, doxazosin, and lisinopril would be better than chlorthalidone.[37] It did not prove this hypothesis because the primary end point was no different between chlorthalidone, amlodipine and lisinopril. Many subgroup analyses of specific populations (e.g., black patients, chronic kidney disease, diabetes) from the ALLHAT have been conducted to assess response in certain unique patient populations.[38–40] Surprisingly, none of these analyses demonstrated superior CV event reductions with lisinopril or amlodipine versus chlorthalidone. Overall, thiazide-type diuretics remain unsurpassed in their ability to reduce CV morbidity and mortality in most patients.

The preponderance of evidence supports the JNC7 recommendation of using a thiazide-type diuretic as a first-line antihypertensive agent, unless there are contraindications or if a compelling indication for another agent is present, for most patients.

CLINICAL CONTROVERSY

Is chlorthalidone superior to hydrochlorothiazide?

Chlorthalidone undisputedly reduces CV morbidity and mortality. It was used in the most influential landmark long-term placebo-controlled trials in hypertension, and is almost twice more potent in lowering BP on a milligram-per-milligram basis than hydrochlorothiazide, which has not been as extensively studied in major long term hypertension clinical trials. In clinical practice, it is well accepted that CV benefits in hypertension apply to all thiazide-type diuretics, and benefits are considered a class effect.[2] However, it is not definitively known if the clinical benefits of reducing CV morbidity and mortality that have been proven with chlorthalidone can be extrapolated to hydrochlorothiazide.

ACE Inhibitors, ARBs, and CCBs as First-Line Agents

Clinical trials data cumulatively demonstrate that ACE inhibitor, CCB, or ARB-based antihypertensive therapy reduces CV events. These agents may be used for patients without compelling indications as a first-line therapy. The Blood Pressure Lowering Treatment Trialists' Collaboration has evaluated the incidence of major CV events and death among different antihypertensive drug classes from 29 major randomized trials in 162,341 patients.[41] In placebo-controlled trials, the incidences of major CV events were significantly lower with ACE inhibitor and CCB-based regimens versus placebo. Although there were differences in the incidences of certain CV events in some comparisons (e.g., stroke was lower with diuretic or CCB-based regiments versus ACE inhibitor-based regimens), there were no differences in total major CV events when ACE inhibitors, CCBs, or diuretics were compared to each other. In studies evaluating ARB-based therapy to control regimens, the incidence of major CV events was lower with ARB-based therapy. However, the control regimens used in these comparisons included both active antihypertensive drug therapies and placebo.

Data from meta-analyses may not be as influential as data from well-designed, prospective, randomized controlled trials (e.g., the ALLHAT). However, they provide clinically useful data that support using ACE inhibitor, CCB, or ARB-based treatment for hypertension as first-line antihypertensive agents. Clinicians can use meta-analyses data as supporting evidence when selecting a first-line antihypertensive regimen for hypertension in most patients.

Other major consensus guidelines recommend multiple first-line options for treating hypertension in most patients. The 2007 European Society of Hypertension-European Society of Cardiology guidelines and the 2006 United Kingdom's National Institute for Health and the Clinical Excellence guidelines list more than one drug therapy option as an acceptable first-line treatment approach.[42,43] The European Society of Hypertension–European Society of Cardiology guidelines are founded on the principle that CV risk reduction is a function of BP control that is largely independent of specific antihypertensives.[42] The United Kingdom guidelines stratify patients based on age and race; they recommend an ACE inhibitor first-line for patients under the age of 55, and either a CCB or thiazide-type diuretic first-line for patients age 55 or older or for black patients.[43]

9 β-Blockers Versus First-Line Agents Clinical trials data cumulatively suggests that β-blockers may not reduce CV events to the extent that ACE inhibitors, CCB, or ARB do. These data are from three meta-analyses of clinical trials evaluating β-blocker-based therapy for hypertension.[44–47] Overall, these analyses demonstrated fewer reductions in CV events with β-blocker-based antihypertensive therapy compared mostly with ACE inhibitor and CCB based therapy. Although comparative data with ARB based therapy are more limited, a similar trend was observed.

Meta-analyses data evaluating β-blockers and their ability to reduce CV events have limitations. Most studies that were included used atenolol as the β-blocker studied. Therefore, it is possible that atenolol is the only β-blocker that reduces CV events less than the other primary antihypertensive drug classes. However, consensus guidelines do extrapolate these findings to the β-blocker drug class in general.[2] The 2006 United Kingdom guidelines recommend a β-blocker only after other primary antihypertensive agents (e.g., thiazide-type diuretics, CCBs, ACE inhibitors, or ARBs) have been used.[43] These findings also call in question the validity of results from prominent prospective, controlled clinical trials evaluating antihypertensive drug therapy that use β-blocker-based therapy, especially atenolol, as the primary comparator.[30,35,47] Of note, these studies used once daily atenolol, which may be inadequate based on the shorter half-life of this agent.

CLINICAL CONTROVERSY

Is atenolol the reason that β-blockers should not be used first-line?

Many of the clinical trials included in the meta-analyses data that suggest β-blocker-based therapy may not reduce CV events as well as these other agents used atenolol dosed once daily.[44–47] Atenolol has a half-life of 6 to 7 hours and is nearly always dosed once daily, while immediate release forms of carvedilol and metoprolol have half-lives 6 to 10 hours and 3 to 7 hours, respectively, and are always dosed at least twice daily. Therefore, it is possible that these findings might only apply to atenolol and also that these findings may be a result of using atenolol once daily instead of twice daily.

β-Blocker therapy for patients without compelling indications still has a role in the management of hypertension. It is important for clinicians to remember that β-blocker-based antihypertensive therapy does not increase risk of CV events; β-blocker-based therapy reduces risk of CV events compared to no antihypertensive therapy. Using a β-blocker as a primary antihypertensive agent is optimal when a thiazide-type diuretic, ACE inhibitor, ARB, or CCB cannot be used as the primary agent. β-blockers still have an important add-on role after first-line agents to reduce BP in patients with hypertension but without compelling indications.

Patients with Compelling Indications[1]

⑩ The JNC7 report identifies six compelling indications. Compelling indications represent specific comorbid conditions where evidence from clinical trials supports using specific antihypertensive classes to treat both the compelling indication and hypertension. Drug therapy recommendations typically consist of combination drug therapies (see Fig. 19–3). Data from these clinical trials have demonstrated reduction in CV morbidity and/or mortality that justify use for patients with hypertension and with such a compelling indication. Some compelling indications include recommendations that are provided by other national treatment guidelines, or from newer clinical trials, which are complementary to the JNC7 guidelines.

Left Ventricular Dysfunction (Systolic Heart Failure)[48] Five drug classes are listed as compelling indications for left ventricular dysfunction [also known as (aka) systolic heart failure]. The primary physiologic abnormality in this compelling indication is decreased CO. Standard pharmacotherapy for left ventricular dysfunction, sometimes called *standard pharmacotherapy*, consists of three drugs: an ACE inhibitor plus diuretic therapy, followed by the addition of an appropriate β-blocker.

Evidence from clinical trials shows that ACE inhibitors significantly modify disease progression by reducing morbidity and mortality. Although left ventricular dysfunction was the primary disease in these studies, ACE inhibitor therapy will also control BP in patients with systolic heart failure and hypertension. ACE inhibitors should be started with low-doses for patients with systolic heart failure, especially those in acute exacerbation. Heart failure induces a compensatory high-renin condition, and starting ACE inhibitors under these conditions can cause a pronounced first-dose effect and possible orthostatic hypotension.

Diuretics are also a part of standard pharmacotherapy primarily to control symptoms. They provide symptomatic relief of edema by inducing diuresis. Loop diuretics are often needed, especially for patients with more advanced heart failure. However, some patients with well-controlled heart failure and without significant chronic kidney disease may be managed with a thiazide-type diuretic.

β-Blocker therapy is appropriate to further modify disease in left ventricular dysfunction and is a component of standard therapy for these patients. For patients on an initial regimen of diuretics and ACE inhibitors, β-blockers have been shown to reduce CV morbidity and mortality.[49,50] It is of paramount importance that β-blockers be dosed appropriately due to the risk of inducing an acute exacerbation of heart failure. They must be started in very low doses, doses much lower than that used to treat hypertension, and titrated slowly to high doses based on tolerability. Bisoprolol, carvedilol, and sustained release metoprolol succinate are the only β-blockers proven to be beneficial in left ventricular dysfunction.[48]

After implementation of a standard three-drug regimen, other agents may be added to further reduce CV morbidity and mortality, and reduce BP if needed. The addition of an aldosterone antagonist can reduce CV morbidity and mortality in left ventricular dysfunction.[51,52] Spironolactone has been studied in severe left ventricular dysfunction and has shown benefit in addition to diuretic and ACE inhibitor therapy.[51] Eplerenone has been studied in patients with symptomatic left ventricular dysfunction within 3 to 14 days after an acute MI in addition to a standard three-drug regimen.[52] An aldosterone antagonist may be considered in addition to a diuretic, ACE inhibitor or ARB, and β-blocker. It is not currently recommended to use both an aldosterone inhibitor and an ARB as add-on therapy to a standard three-drug regimen because of the potential increase in risk of severe hyperkalemia.[48]

Early data suggested that ARBs may be better than ACE inhibitors in left ventricular dysfunction.[53] However, when directly compared in a well-designed prospective trial, ACE inhibitors were found to be better.[54] ARBs are acceptable as an alternative therapy for patients who cannot tolerate ACE inhibitors and possibly as add-on therapy to those already on a standard three-drug regimen based on data from the Candesartan in Heart Failure-Assessment of Reduction in Mortality and Morbidity (CHARM) studies.[55,56] However, the clinical benefit of adding an ARB to a regimen that already includes an ACE inhibitor seems to be limited to reducing the incidence of hospitalization for heart failure. Therefore, if a fourth agent needs to be added, many clinicians will select an aldosterone antagonist. For patients self-described as African-Americans, the combination of a fixed dose of isosorbide dinitrate and hydralazine to standard three drug regimen is recommended as an option to improve CV outcomes.[48]

Post-MI[57] β-Blocker [those without intrinsic sympathomimetic activity (ISA)] and ACE inhibitor therapy are recommended in the AHA/American College of Cardiology and JNC7 guidelines.[1,2,57] β-blockers decrease cardiac adrenergic stimulation and have been shown in clinical trials to reduce the risk of a subsequent MI or sudden cardiac death. ACE inhibitors have been shown to improve cardiac remodeling and cardiac function and to reduce CV events post-MI. These two drug classes, with β-blockers first, are considered the first drugs of choice for patients who have experienced an MI. One study, the Valsartan in acute MI (VALIANT) trial, demonstrated that ARB therapy is similar to ACE inhibitor therapy for patients post-MI with left ventricular dysfunction.[58] However, ARBs are considered alternatives to ACE inhibitors in post-MI patients with left ventricular dysfunction.

Eplerenone reduces CV morbidity and mortality in patients soon after an acute MI (within 3 to 14 days).[52] However, this supporting evidence was specifically for patients with symptoms of acute left ventricular dysfunction. Considering that this drug has the propensity to cause significant hyperkalemia, eplerenone should only be used in selected patients following an MI and left ventricular dysfunction with very diligent monitoring of potassium.

Coronary Artery Disease[57,59] Chronic stable angina and acute coronary syndrome (unstable angina and acute MI) are forms of coronary artery disease (aka ischemic heart disease). These are the most common forms of hypertension-associated target-organ disease. This compelling indication is also referred to as high coronary disease risk and high CV disease risk in the JNC7 report.[1] This compelling indication does not refer to patients without established CV disease (primary prevention patients) even if they have very high Framingham risk score (e.g., greater than 20%). β-Blocker therapy has the most evidence demonstrating benefits in these patients. β-blockers are first-line therapy in chronic stable angina and have the ability to reduce BP and improve ischemic symptoms by decreasing myocardial oxygen consumption and demand.

Long-acting CCBs are either alternatives (the nondihydropyridine CCBs diltiazem and verapamil) or add-on therapy (dihydropyridine CCBs) to β-blockers in chronic stable angina for patients with ischemic symptoms.[59] The International Verapamil-Trandolapril Study (INVEST) demonstrated no difference in CV risk reduction

when β-blocker-based therapy was compared to nondihydropyridine CCB-based therapy in this population.[60] Nonetheless, the preponderance of data are with β-blockers and they remain the therapy of choice.[1,57,59]

For acute coronary syndromes (ST-elevation MI and unstable angina/non-ST-segment MI), first-line therapy should consist of a β-blocker and ACE inhibitor.[61,62] This regimen will lower BP, control acute ischemia, and reduce CV risk.

CCBs (especially nondihydropyridine CCBs) and β-blockers provide anti-ischemic effects; they lower BP and reduce myocardial oxygen demand in patients with hypertension and coronary artery disease. However, cardiac stimulation may occur with dihydropyridine CCBs or β-blockers with ISA, making these agents less desirable. Therefore, β-blockers with ISA should be avoided. Nondihydropyridines CCBs should be used as alternatives to β-blockers, and dihydropyridines should be add-on therapy to β-blockers.

Once ischemic symptoms are controlled with β-blocker and/or CCB therapy, other antihypertensive drugs can be added to provide additional CV risk reduction. Clinical trials have demonstrated that the addition of an ACE inhibitor further reduces risk CV events in patients with chronic stable angina.[63] ARBs may provide similar benefits but have not been as extensively studied as ACE inhibitors have in clinical trials.[63] Therefore, in coronary artery disease, ARBs are generally considered an alternative to ACE inhibitor therapy. Thiazide-type diuretics can be added thereafter to provide additional BP lowering and to further reduce CV risk; they do not provide anti-ischemic effects.

Diabetes Mellitus[1,21] The primary cause of mortality in diabetes is CV disease, and hypertension management is a very important risk-reduction strategy. Five antihypertensive agents have evidence supporting their compelling indications in diabetes (see Fig. 19–3). All of these agents have been shown to reduce CV events in patients with diabetes. However, risk reduction may not be equal when comparing these agents.

11 All patients with diabetes and hypertension should be treated with an ACE inhibitor or an ARB.[21] Pharmacologically, both of these agents should provide nephro protection due to vasodilatation in the efferent arteriole of the kidney. Moreover, ACE inhibitors have overwhelming data demonstrating CV risk reduction in patients with established forms of heart disease. Evidence from outcome studies have demonstrated reductions in both CV risk (mostly with ACE inhibitors) and reduction in risk of progressive kidney dysfunction (mostly with ARBs) in patients with diabetes.[21] There is debate surrounding which agent is better because data support both drug classes. Nonetheless, either drug class should be used to control BP as one of the drugs in the antihypertensive regimen for patients with diabetes because multiple agents are often needed to attain goal BP values.

A thiazide-type diuretic is recommended as the second agent to lower BP and provide additional CV risk-reduction. A subgroup analysis of patients with diabetes from the ALLHAT trial showed no difference in long-term risk of CV events in the chlorthalidone and lisinopril treatment groups.[39] Therefore, some argue that thiazide-type diuretics, used in low-doses, are equally effective for patients with hypertension and diabetes. Nonetheless, the entire body of evidence evaluating pharmacotherapy for patients with hypertension and diabetes and consensus guidelines support an ACE inhibitor or ARB first-line, with a thiazide-type diuretic as add-on therapy.[1,21,64]

CCBs are useful add-on agents for BP control for patients with diabetes. Several studies have compared an ACE inhibitor with either a dihydropyridine CCB or a β-blocker. In the studies comparing a dihydropyridine with an ACE inhibitor, the ACE inhibitor group had significantly lower rates of CV end points, including MIs and all CV events.[65] These data do not suggest that CCBs are harmful in patients with diabetes, but indicate that they are not as protective as ACE inhibitors. While data are limited, nondihydropyridine CCBs (diltiazem and verapamil) appear to have more renal protective effects than the dihydropyridines.[64]

β-blockers, similar to CCBs, are useful add-on agents for BP control for patients with diabetes. These agents should also be used to treat another compelling indication (e.g., post-MI). β-blockers (especially non-selective agents) can possibly mask the signs and symptoms of hypoglycemia in patients with tightly controlled diabetes because most of the symptoms of hypoglycemia (i.e., tremor, tachycardia, and palpitations) are mediated through the sympathetic nervous system. Sweating, a cholinergically mediated symptom of hypoglycemia, should still occur during a hypoglycemic episode despite β-blocker therapy. Patients may also have a delay in hypoglycemia recovery time because compensatory recovery mechanisms need the catecholamine inputs that are antagonized by β-blocker therapy. Finally, unopposed α-receptor stimulation during the acute hypoglycemic recovery phase (due to endogenous epinephrine release intended to reverse hypoglycemia) may result in acutely elevated BP due to vasoconstriction. Despite these potential problems, β-blockers can be safely used for patients with diabetes.

Based on the weight of all evidence, ACE inhibitors or ARBs are preferred first-line agents for controlling hypertension in diabetes. The need for combination therapy should be anticipated, and thiazide-type diuretics should the second agent added. Based on scientific evidence, CCBs and even β-blockers are useful evidenced-based agents in this population, but are considered add-on therapies to the aforementioned agents.

Chronic Kidney Disease[66] Patients with hypertension may develop damage to either the renal tissue (parenchyma) or the renal arteries. Chronic kidney disease initially presents as microalbuminuria (30 to 299 mcg/mg albumin/creatinine ratio on a spot urine sample or greater than or equal 30 mg albumin in a 24 hour urine collection) that can progress to overt kidney failure. The rate of kidney function deterioration is accelerated when both hypertension and diabetes are present. Once patients have an estimated GFR less than 60 mL/min/1.73 m^2 or albuminuria they have significant chronic kidney disease and risk of CV disease and progression to severe chronic kidney disease increases.[1]

BP control to a goal of less than 130/80 mm Hg can slow the decline in kidney function. Although this BP goal is recommended in significant chronic kidney disease, long term benefits of this BP goal have mostly been demonstrated for patients with both significant chronic kidney disease and diabetes.[67]

In addition to lowering BP, ACE inhibitors and ARBs reduce intraglomerular pressure, which can theoretically provide additional benefits by further reducing the decline in kidney function. ACE inhibitors and ARBs have been shown to reduce progression of chronic kidney disease in diabetes[21] and in those without diabetes.[64,68] It is difficult to differentiate whether the kidney protection benefits are from RAAS blockade versus BP lowering. A meta-analysis failed to demonstrate any unique long term kidney protective effects of RAAS blocking drugs compared with other antihypertensive drugs.[69] Moreover, a subgroup analysis of patients from the ALLHAT stratified by different baseline GFR values also did not show a difference in long term outcomes with chlorthalidone versus lisinopril.[38] Nonetheless, consensus guidelines recommend either an ACE inhibitor or ARB as first-line therapy to control BP and preserve kidney function in chronic kidney disease.

Patients may experience a rapid and profound drop in BP or acute kidney failure when given an ACE inhibitor or ARB. The potential to produce acute kidney failure is particularly problematic in patients with bilateral renal artery stenosis or a solitary functioning kidney

with stenosis. Patients with renal artery stenosis are usually older, and the condition is more common in patients with diabetes or those who smoke. Patients with renal artery stenosis do not always have evidence of kidney disease unless sophisticated tests are performed. Starting with low dosages and evaluating serum creatinine soon after starting the drug can minimize this risk.

Recurrent Stroke Prevention Stroke (specifically ischemic stroke, not hemorrhagic stroke) is considered a form of hypertension-associated target organ damage. Attaining goal BP values in patients who have experienced an ischemic stroke is considered a primary modality to reduce risk of a second stroke. However, BP lowering should only be attempted after patients have stabilized following an acute cerebrovascular event. One clinical trial, the Protection Against Recurrent Stroke Study (PROGRESS), showed that the incidence of recurrent stroke in patients with a history of ischemic stroke can be reduced when a thiazide-type diuretic is added to an ACE inhibitor.[32] Reduction in recurrent stroke was seen with this combination therapy, even in those who had BP values less than 140/90 mm Hg. Recurrent stroke was not reduced with ACE inhibitor monotherapy in the PROGRESS; it was only reduced when the thiazide-type diuretic was added.

An ACE inhibitor with a thiazide-type diuretic is an evidence-based antihypertensive regimen for patients with a history of cerebrovascular disease.[1,70] This recommendation does not apply to patients with a history of hemorrhagic stroke. However, it does apply to patients with a history of transient ischemic attack, which is considered a form of this compelling indication.

CLINICAL CONTROVERSY

Does ARB-based therapy reduce recurrent stroke risk?

Two large, prospective clinical trials have evaluated whether ARB-based therapy reduces the risk of recurrent stroke in patients with established cerebrovascular disease. In the Morbidity and Mortality after Stroke- Eprosartan Compared With Nitrendipine for Secondary Prevention (MOSES) study, patients with a history of cerebrovascular disease (ischemic stroke or transient ischemic attack) had a lower risk of a recurrent stoke when treated with ARB-based therapy compared to dihydropyridine CCB-based therapy.[71] However, in the PROFESS trial, there was no difference in the incidence of recurrent stroke with ARB-based treatment versus placebo.[72] Therefore, the exact role of ARB-based therapy for patients with a history of ischemic stroke is unknown.

Alternative Drug Treatments

It is necessary to use other agents such as a direct renin inhibitor, α-blockers, central α_2-agonists, adrenergic inhibitors, and arterial vasodilators in some patients. Although these agents are effective in lowering BP, they do not have compelling outcome data showing reduced morbidity and mortality in hypertension. Moreover, there is a much greater incidence of adverse effects with some of these agents (i.e., α-blockers, central α_2-agonists, and arterial vasodilators) than with first-line agents. They are generally reserved for patients with resistant hypertension or as add-on therapy with multiple other primary antihypertensive agents.

Special Populations[1] Selection of drug therapy should follow the guidelines provided by the JNC7 and AHA 2007 recommendations, which are summarized in Figures 19–2 and 19–3. These should be maintained as the guiding principles of drug therapy. However, there are some patient populations where the approach to drug therapy may be slightly different or utilize recommended agents using tailored dosing strategies. In some cases, this is because other agents have unique properties that benefit a coexisting condition, but may not be based on evidence from outcome studies in hypertension.

Hypertension in Older People Hypertension often presents as isolated systolic hypertension in the elderly. Epidemiologic data indicate that CV morbidity and mortality are more directly correlated to SBP than to DBP for patients age 50 and older, so this population is at high risk for hypertension related target-organ damage.[1] Although several placebo-controlled trials have specifically demonstrated risk reduction in this form of hypertension, many older people with hypertension are either not treated, or treated yet not controlled.[73]

The SHEP was a landmark double-blind, placebo-controlled trial that evaluated chlorthalidone-based treatment (with atenolol or reserpine as add-on therapy) for isolated systolic hypertension.[8] A 36% reduction in total stroke, a 27% reduction in coronary artery disease, and 55% reduction in heart failure were demonstrated versus placebo. The Systolic Hypertension in Europe (Syst-Eur) trial was another placebo-controlled trial that evaluated treatment with a long acting dihydropyridine CCB.[11] Treatment resulted in a 42% reduction in stroke, 26% reduction in coronary artery disease, and 29% reduction in heart failure. These data clearly demonstrate reductions in CV morbidity and mortality in older patients with isolated systolic hypertension, especially with thiazide-type diuretics and long-acting dihydropyridine CCBs.

The very elderly population, greater than or equal 80 years, were underrepresented in the SHEP and Syst-Eur studies. Historically, this population often is not treated to goal either because of a fear of side effects or because of limited data demonstrating benefit. However, the Hypertension in the Very Elderly Trial (HYVET) in 2008 provided definitive proof that antihypertensive drug therapy provides significant clinical benefits in the very elderly.[74] The HYVET was a prospective controlled clinical trial that randomized patients 80 years and older with hypertension to placebo or antihypertensive drug therapy. It was stopped early after a median of only 1.8 years because the incidence of death was 21% higher in placebo-treated patients. Based on these results, hypertension should be treated in the very elderly.

CLINICAL CONTROVERSY

How aggressively should BP be lowered in the very elderly?

It has been advocated for several years to target standard BP goals in the elderly population, regardless of age. This is a well-accepted standard of care for patients with hypertension that continue to have hypertension as they age, meaning that a patient with a history of hypertension should not have their BP goal adjusted just because they have become older. However, for patients that initially develop hypertension when they are very elderly, it is less clear what their BP goal should be. The HYVET trial established that treating hypertension in patients age 80 years or older reduces mortality, but the treatment goal in that population was less than 150/80 mm Hg with a mean SBP and DBP achieved of 145 mm Hg and 79 mm Hg, respectively at 2 years.

Thiazide-type diuretics or β-blockers have been compared with either ACE inhibitors or CCBs in elderly patients with either systolic or diastolic hypertension or both in the Swedish Trial in Old Patients with Hypertension-2 (STOP-2) study.[75] In this trial no significant differences were seen between conventional drugs and either ACE inhibitors or CCBs. However, there were significantly fewer MIs and cases of heart failure in the ACE inhibitor group compared with the CCB group. These data suggest that overall treatment may be more important than specific antihypertensive agents in this population.

Elderly patients are more sensitive to volume depletion and sympathetic inhibition than younger patients. This may lead to orthostatic hypotension (see next section). In the elderly, this can increase the risk of falls due to the associated dizziness. Centrally acting agents and α-blockers should generally be avoided or used with caution in the elderly because they are frequently associated with dizziness and orthostatic hypotension. Diuretics, ACE inhibitors, and ARBs provide significant benefits and can safely be used in the elderly, but smaller-than-usual initial doses must be used for initial therapy.

The JNC7 and AHA goal BP recommendations are independent of age.[1,2] Age adjusted goals are currently not appropriate. Moreover, treatment of hypertension in older patients should follow the same principles that are outlined for general care of hypertension. However, initial drug doses may be lower, and dosage titrations over a longer period of time to minimize the risk of hypotension are usually needed.

⓬ Patients at Risk for Orthostatic Hypotension *Orthostatic hypotension* is a significant drop in BP when standing and can be associated with dizziness and/or fainting. It is defined as an SBP decrease of greater than 20 mm Hg or DBP decrease of greater than 10 mm Hg when changing from supine to standing.[1] Older patients (especially those with isolated systolic hypotension) and patients with diabetes, severe volume depletion, baroreflex dysfunction, autonomic insufficiency, and use of venodilators (α-blockers, mixed α-/β-blockers, nitrates, and phosphodiesterase inhibitors) all increase risk of orthostatic hypotension. For patients with these risks, antihypertensive agents should be started in low doses, especially diuretics, ACE inhibitors, and ARBs.

Hypertension in Children and Adolescents[76] Detecting hypertension in children requires special attention to BP measurement, which is defined as SBP and/or DBP that is greater than 95th percentile for sex, age, and height on at least three occasions.[76] Blood pressure between the 90th and 95th percentile, or greater than 120/80 mmHg in adolescents, is considered prehypertension. Hypertensive children often have a family history of high BP, and many are overweight predisposing them to insulin resistance and associated CV disease. Unlike hypertension in adults, secondary hypertension is more common in children and adolescents. An appropriate workup for secondary causes is required if elevated BP is identified. Kidney disease (e.g., pyelonephritis, glomerulonephritis) is the most common cause of secondary hypertension in children. Coarctation of the aorta can also produce secondary hypertension. Medical or surgical management of the underlying disorder usually normalizes BP.

Non-pharmacologic treatment, particularly weight loss in those overweight, is the cornerstone of therapy for essential hypertension in children.[76] The goal is to reduce the BP to below the 95th percentile for sex, age, and height, or below the 90th percentile if concurrent conditions such as chronic kidney disease, diabetes, or target organ damage are present. ACE inhibitors, ARBs, β-blockers, CCBs, and thiazide-type diuretics are all acceptable choices in children and have data supporting their use. ACE inhibitors and ARBs are contraindicated in sexually active girls due to potential teratogenic effect. As with adults, selection of initial agents should be based on the presence of compelling indications or concurrent conditions that may warrant their use (e.g., ACE inhibitor or ARB for those with diabetes or microalbuminuria).

Pregnancy[1,77] Hypertension during pregnancy is a major cause of maternal and neonatal morbidity and mortality. Hypertension during pregnancy is categorized as preeclampsia, eclampsia, gestational, chronic, and superimposition of preeclampsia on chronic hypertension. *Preeclampsia*, defined as an elevated BP greater than 140/90 that appears after 20 weeks gestation accompanied by new-onset proteinuria (greater than or equal to 300 mg/24 hours), can lead to life-threatening complications for both mother and fetus. Eclampsia, the onset of convulsions in preeclampsia, is a medical emergency. *Gestational hypertension* is defined as new onset hypertension arising after mid-pregnancy in the absence of proteinuria, and chronic hypertension is elevated BP that is noted before the pregnancy began. It is controversial whether treating elevated BP for patients with chronic hypertension in pregnancy is beneficial. However, women with chronic hypertension prior to pregnancy are at increased risk of a number of complications including superimposed preeclampsia, preterm delivery, fetal growth restriction or demise, placental abruption, heart failure, and acute kidney failure.[77]

Definitive treatment of preeclampsia is delivery. Delivery is indicated if pending or frank eclampsia is present. Otherwise, management consists of restricting activity, bed rest, and close monitoring. Salt restriction, or any other measures that contract blood volume, should not be employed. Antihypertensive agents are used prior to induction of labor if DBP is greater than 105 mm Hg with a target DBP of 95 to 105 mm Hg. Intravenous hydralazine is most commonly used, and intravenous labetalol is also effective. Immediate-release oral nifedipine has been used in the past, but it is not approved by the Food and Drug Administration (FDA) for hypertension, and untoward fetal and maternal effects (hypotension with fetal distress) have been reported.

Many agents can be used to treat chronic hypertension in pregnancy (Table 19–7). Unfortunately, there is little consensus and few data regarding the most appropriate therapy in pregnancy. Methyldopa is still considered the drug of choice.[1] It is viewed as very safe based on long-term follow-up data (7.5 years) that has not demonstrated adverse effects on childhood development. β-blockers (other than atenolol), labetalol and CCBs are also reasonable alternatives. ACE inhibitors and ARBs are known teratogens and are absolutely contraindicated.[78]

African-Americans[1,79] Hypertension affects African-American patients at a disproportionately higher rate, and hypertension-related target-organ damage is more prevalent than in other populations. Reasons for these differences are not fully understood, but may be related to differences in electrolyte homeostasis, GFR, sodium excretion and transport mechanisms, plasma renin activity, and BP response to plasma volume expansion.

African-Americans have an increased need for combination therapy to attain and maintain BP goals.[79] The Hypertension in African American Working Group of the International Society on

TABLE 19-7 Treatment of Chronic Hypertension in Pregnancy

Drug/Class	Comments
Methyldopa	Preferred agent based on long-term follow-up data supporting safety; traditional drug of choice
β-blockers	Generally safe, but intrauterine growth retardation reported (mostly with atenolol)
Labetalol	Increasingly preferred over methyldopa because of fewer side effects
Clonidine	Limited data available; used mainly in third trimester
CCBs	Limited data available; no increase in major teratogenicity with exposure (except immediate-release oral nifedipine should not be used)
Diuretics	Not first-line agents but probably safe in low doses if started prior to conception for essential hypertension
ACE inhibitors, ARBs, direct renin inhibitors	Contraindicated; major teratogenicity reported with exposure (fetal toxicity and death)

Hypertension in Blacks published treatment guidelines that are similar to the JNC7.[79] Lifestyle modifications are recommended to augment drug therapy. They support thiazide-type diuretics as first-line for most patients and selecting specific drug therapy to treat compelling indications, if present. These guidelines aggressively promote combination therapy. They recommend starting with two drugs for patients with SBP values greater than or equal to 15 mm Hg from goal. This aggressive approach is reasonable considering that overall goal BP attainment rates are low in African-Americans.

BP lowering effects of antihypertensive classes varies in African-Americans, primarily when used as monotherapy. Thiazide diuretics and CCBs are most effective at lowering BP in African-Americans. When either of these two classes (especially thiazide-type diuretics) are used in combination with a β-blocker, ACE inhibitor, or ARB (which are three classes known to be less effective at lowering BP in African-Americans), antihypertensive response is significantly increased. This may be due to the low-renin pattern of hypertension in African Americans, which can result in less BP lowering with β-blockers, ACE inhibitors, or ARBs when used as monotherapy compared to Caucasian patients. Interestingly, African-Americans have a higher risk of angioedema and cough from ACE inhibitors compared with Caucasians.[79]

Despite potential differences in antihypertensive effects, drug therapy selection should be based upon evidence, no different from what is recommended for the hypertensive population in general. Drug therapies should be used if a compelling indication is present, even if antihypertensive effect may not be as great as with another drug class (e.g., a β-blocker is first line for BP control in a African-American patient who is post-MI).

Other Concomitant Conditions

Most patients with hypertension have some other coexisting conditions that may influence selection or utilization of drug therapy. The influence of concomitant conditions should only be complementary to, and never in replacement of, drug therapy choices indicated by compelling indications. Under some circumstances, these considerations are helpful in deciding on a particular antihypertensive agent when more than one antihypertensive class is recommended to treat a compelling indication. In some cases, an agent should be avoided because it may aggravate a concomitant disorder. In other cases, an antihypertensive can be used to treat hypertension, a compelling indication, and another concomitant condition. These are briefly summarized in Table 19–5.

Pulmonary Disease and Peripheral Arterial Disease[80] β-blockers, especially non-selective agents, have been generally avoided for patients with hypertension and reactive airway disease (asthma or chronic obstructive pulmonary disease [COPD] with a reversible obstructive component) due to a fear of inducing bronchospasm. This precaution is more of a myth than a fact. Data suggests that cardioselective β-blockers can safely be used in patients with asthma or COPD.[81] Therefore cardioselective β-blockers should be used to treat a compelling indication (i.e., post-MI, coronary disease, or heart failure) for patients with reactive airway disease.

Peripheral arterial disease (PAD) is considered a noncoronary form of atherosclerotic vascular disease and is a coronary artery disease risk equivalent. ACE inhibitors may be ideal for patients with symptomatic lower extremity PAD who also have hypertension, as they have been shown to decrease CV events in these patients.[80] β-blockers can theoretically be problematic for patients with PAD due to possible decreased peripheral blood flow secondary to unopposed stimulation of α-receptors that results in vasoconstriction. If problematic, this can be mitigated by using a β-blocker that also has α-blocking properties (e.g., carvedilol). However, β-blockers are not contraindicated in PAD and have not been shown to adversely affect walking capacity.[80]

Metabolic Syndrome[12] Metabolic syndrome is a cluster of multiple cardiometabolic risk factors. It has been most recently defined as the presence of 3 of the following 5 criteria: abdominal obesity (based on waist circumference measurements), elevated triglycerides, low HDL cholesterol, elevated BP (≥130/≥85 mm Hg or receiving drug treatment for high BP), and elevated fasting blood glucose.[12]

Despite the debate regarding whether or not metabolic syndrome is a true "disease" or rather simply a cluster of risk factors, it is widely accepted that patients with metabolic syndrome have increased risk of developing CV disease and/or type 2 diabetes. Using an ACE inhibitor or ARB is associated with the lowest rate of developing new onset diabetes in patients with hypertension.[82] However, studies specifically evaluating the most effective antihypertensive regimen for patients with metabolic syndrome have not been done. In addition, an ALLHAT subgroup analysis of patients with impaired fasting glucose showed that CV events were reduced more with chlorthalidone compared to lisinopril.[39] Thus, thiazide-type diuretics can be used first line for patients with metabolic syndrome, similar to ACE inhibitors, ARBs, or CCBs, but treated patients will have a higher risk of developing elevated fasting glucose.

Erectile Dysfunction[83] Most antihypertensive agents have been associated with erectile dysfunction in men. However, it is not clear if erectile dysfunction associated with antihypertensive treatment is solely a result of drug therapy or rather a symptom of underlying CV disease. β-blockers have traditionally been labeled as agents that significantly cause sexual dysfunction, and many practitioners have avoided prescribing them as a result. However, data supporting this notion are limited. A systematic review of 15 studies involving 35,000 patients assessing β-blocker use for MI, heart failure, and hypertension found only a very slight increased risk for erectile dysfunction.[84] In addition, prospective long-term data from the Treatment of Mild Hypertension Study (TOMHS) and the Veterans Administration Cooperative trial show no difference in the incidence of erectile dysfunction between diuretics and β-blockers versus ACE inhibitors and CCBs.[85,86] Centrally acting agents are associated with higher rates of sexual dysfunction and should be avoided in men with erectile dysfunction.

Hypertensive men frequently have atherosclerotic vascular disease, which frequently results in erectile dysfunction. Therefore, erectile dysfunction is associated with chronic arterial changes resulting from elevated BP, and lack of control may increase the risk of erectile dysfunction. These changes are even more pronounced in hypertensive men with diabetes.

Individual Antihypertensive Agents[1,6]

Diuretics[87] There are four subclasses of diuretics that are used in the treatment of hypertension: thiazide-type diuretics, loops, potassium-sparing agents, and aldosterone antagonists (see Table 19–5). Thiazide-type diuretics are the preferred type of diuretic for most patients with hypertension.[1,2] The best available evidence justifying this recommendation is from ALLHAT.[31] Moreover, when combination therapy is needed in hypertension to control BP, a thiazide-type diuretic as the second agent is very effective in lowering BP.[1,88]

Loops are more potent agents for inducing a diuresis, but they are not ideal antihypertensive agents unless relief of edema is also needed. In general, loops are often preferred over a thiazide-type diuretic for hypertension in patients with chronic kidney disease when estimated GFR is less than 30 mL/min/1.73 m^2.[87]

CLINICAL CONTROVERSY

Are loop diuretics always preferred over thiazide-type diuretics in chronic kidney disease?

Thiazide-type diuretics have been traditionally viewed as less effective compared with loop diuretics for patients with severe chronic kidney disease. Some clinicians routinely replace thiazide-type diuretics with a loop diuretic for patients that have estimated creatinine clearances below 30 mL/min. However, limited data demonstrate that hydrochlorothiazide is equally effective for BP lowering when compared with furosemide for patients with severe renal failure and hypertension.[89]

Potassium-sparing diuretics are very weak antihypertensive agents when used alone but provide minimal additive effect when used in combination with a thiazide or loop diuretic. Their primary use in combination with another diuretic is to counteract the potassium-wasting properties of the other diuretic agents. Aldosterone antagonists (spironolactone and eplerenone) may be technically considered potassium-sparing agents but are more potent as antihypertensives. However, they are viewed by the JNC7 as an independent class due to evidence supporting compelling indications.

The exact hypotensive mechanism of action of diuretics is not known, but has been well hypothesized. The drop in BP seen when diuretics are first started is caused by an initial diuresis. Diuresis causes reductions in plasma and stroke volume, which decreases CO and BP. This initial drop in CO causes a compensatory increase in peripheral vascular resistance. With chronic diuretic therapy, extracellular fluid and plasma volume return to near pretreatment values. However, peripheral vascular resistance decreases to values that are lower than the pretreatment baseline. This reduction in peripheral vascular resistance is responsible for chronic antihypertensive effects.

Thiazide-type diuretics have additional actions that may further explain their antihypertensive effects. Thiazide-type diuretics mobilize sodium and water from arteriolar walls. This effect would lessen the amount of physical encroachment on the lumen of the vessel created by excessive accumulation of intracellular fluid. As the diameter of the lumen relaxes and increases, there is less resistance to the flow of blood and peripheral vascular resistance further drops. High dietary sodium intake can blunt this effect and a low salt intake can enhance this effect. Thiazide-type diuretics are also postulated to cause direct relaxation of vascular smooth muscle.

Diuretics should ideally be dosed in the morning if given once daily and in the morning and late afternoon when dosed twice daily to minimize risk of nocturnal diuresis. However, with chronic use, thiazide-type diuretics, potassium sparing diuretics, and aldosterone antagonists rarely cause a pronounced diuresis.

The major pharmacokinetic differences between the various thiazide-type diuretics are serum half-life and duration of diuretic effect. The clinical relevance of these differences is unknown because the serum half-life of most antihypertensive agents does not correlate with the hypotensive duration of action. Moreover, diuretics lower BP primarily through extrarenal mechanisms. Hydrochlorothiazide and particularly chlorthalidone are the two most frequently used thiazide diuretics in landmark clinical trials that have demonstrated reduced morbidity and mortality. These agents are not equipotent on a milligram-per-milligram basis; chlorthalidone is 1.5 to 2.0 times more potent than hydrochlorothiazide.[87,90] This has been attributed to a longer half-life (45 to 60 hours vs 8 to 15 hours) and longer duration of effect (48 to 72 hours vs 16 to 24 hours) with chlorthalidone.

Diuretics are very effective in lowering BP when used in combination with most other antihypertensives.[88] This additive response is explained by two independent pharmacodynamic effects. First, when two drugs cause the same overall pharmacologic effect (BP lowering) through different mechanisms of action, their combination usually results in an additive or synergistic effect. This is especially relevant when a β-blocker or ACE inhibitor is indicated in an African-American, but does not elicit sufficient antihypertensive effect. Adding a diuretic in this situation can often significantly lower BP. Second, a compensatory increase in sodium and fluid retention may be seen with antihypertensive agents. This problem is counteracted with the concurrent use of a diuretic.

The side effects of thiazide-type diuretics include hypokalemia, hypomagnesemia, hypercalcemia, hyperuricemia, hyperglycemia, dyslipidemia, and sexual dysfunction. Many of these side effects were identified when high-doses of thiazides were used in the past (e.g., hydrochlorothiazide 100 mg/day). Current guidelines recommend limiting the dose of hydrochlorothiazide or chlorthalidone to 12.5 to 25 mg/day, which markedly reduces the risk for most metabolic side effects. Loop diuretics may cause the same side effects, although the effect on serum lipids and glucose is not as significant, hypokalemia is more pronounced and hypocalcemia may occur.

Hypokalemia and hypomagnesemia may cause muscle fatigue or cramps. However, serious cardiac arrhythmias can occur in patients with severe hypokalemia and hypomagnesemia. Patients at greatest risk for this are patients with LVH, coronary disease, post-MI, a history of arrhythmia, or those concurrently receiving digoxin. Low-dose therapy (i.e., 25 mg hydrochlorothiazide or 12.5 mg chlorthalidone daily) causes small electrolyte disturbances. Efforts should be made to keep potassium in the therapeutic range by careful monitoring.

Diuretic-induced hyperuricemia can precipitate gout. This side effect may be especially problematic for patients with a previous history of gout and is more common with thiazide-type diuretics. However, acute gout is unlikely in patients with no previous history of gout. If gout does occur in a patient who requires diuretic therapy, allopurinol can be given to prevent gout and will not compromise the antihypertensive effects of the diuretic. High doses of thiazide-type and loop diuretics may increase fasting glucose and serum cholesterol values. These effects, however, usually are transient and often inconsequential.[91]

Potassium-sparing diuretics can cause hyperkalemia, especially in patients with chronic kidney disease or diabetes and in patients receiving concurrent treatment with an ACE inhibitor, ARB, direct renin inhibitor, or potassium supplements. Hyperkalemia is especially problematic for the newest aldosterone antagonist eplerenone. This agent is a very selective aldosterone antagonist, and its propensity to cause hyperkalemia is greater than with the other potassium sparing agents and even spironolactone. Due to this increased risk of hyperkalemia, eplerenone is contraindicated for patients with impaired kidney function or type 2 diabetes with proteinuria (see Table 19–5). While spironolactone may cause gynecomastia in up to 10% of patients, this occurs rarely with eplerenone.

Diuretics can be used safely with most other agents. However, concurrent administration with lithium may result in increased lithium serum concentrations and can predispose patients to lithium toxicity.

Minimizing Hyperglycemia with Thiazide-type Diuretic Therapy Patients treated with thiazide-type diuretic therapy have a higher incidence of developing type 2 diabetes than patients treated with other antihypertensive therapies.[82] There is a plausible theory that insulin utilization is linked to intracellular potassium. This increase in risk has been associated with potassium concentrations and hypokalemia.[92] Patients that are treated with a thiazide-type diuretic and have the lowest serum

potassium concentrations have the largest increases in glucose concentrations. The potassium cut point at which this relationship appears is when serum potassium is less than 4.0 mEq/L.

Despite the increased risk of hyperglycemia, and possibly development of type 2 diabetes, thiazide-type diuretics must still be used as a first-line drug therapy option for many patients with hypertension. However, clinicians should be proactive in trying to minimize potential hyperglycemia. Three strategies might be considered as modalities to minimize thiazide induced hyperglycemia: (1) use the lowest effective dose (e.g., hydrochlorothiazide 12.5 or 25 mg daily), (2) maintain serum potassium values between 4.0 and 5.0 mEq/L during treatment with a thiazide type diuretic, and (3) lifestyle modification.[93] While these strategies are not definitively proven to reduce risk of hyperglycemia and progression to type 2 diabetes, they are considered reasonable in the overall care of patients with hypertension. Moreover, other than potassium supplementation, the other strategies that would maintain serum potassium between 4.0 and 5.0 mEq/L could be accomplished by adding an ACE inhibitor, ARB, or potassium sparing drug. These additional drug therapies are easily available in fixed dose combination products and may aid in achieving BP goals for patients with hypertension.

ACE Inhibitors ACE inhibitors are a first-line therapy option in most patients with hypertension.[1,2] The ALLHAT demonstrated less heart failure and stroke with chlorthalidone versus lisinopril.[31] However, another outcome study has demonstrated similar, if not better outcomes with ACE inhibitors versus hydrochlorothiazide.[33] It is possible that the different thiazide-type diuretics have different abilities to reduce hypertension associated target organ damage. Nonetheless, most clinicians will agree that if ACE inhibitors are not the first agent used in most patients with hypertension, they should be the second agent used.

ACE facilitates production of angiotensin II that has a major role in arterial BP regulation as depicted in Figure 19–1. ACE is distributed in many tissues and is present in several different cell types, but its principal location is in endothelial cells. Therefore, the major site for angiotensin II production is in the blood vessels, not the kidney. ACE inhibitors block the ACE, thus inhibiting conversion of angiotensin I to angiotensin II. Angiotensin II is a potent vasoconstrictor that stimulates aldosterone secretion, causing an increase in sodium and water reabsorption with accompanying potassium loss. By blocking the ACE, vasodilatation and a decrease in aldosterone occur.

ACE inhibitors also block degradation of bradykinin and stimulate the synthesis of other vasodilating substances (prostaglandin E_2 and prostacyclin). The observation that ACE inhibitors lower BP in patients with normal plasma renin activity suggests that bradykinin and perhaps tissue production of ACE are important in hypertension. Increased bradykinin enhances the BP lowering effects of ACE inhibitors, but also is responsible for the side effect of dry cough. ACE inhibitors effectively prevent or regress LVH by reducing direct stimulation by angiotensin II on myocardial cells.

There are many evidence-based uses for ACE inhibitors (see Fig. 19–3). ACE inhibitors reduce CV morbidity and mortality in patients with left ventricular dysfunction,[48] and decrease progression of chronic kidney disease.[64] They should be first-line as disease modifying therapy in all of these patients unless absolutely contraindicated. ACE inhibitors (or ARBs in certain patients), are first-line for patients with diabetes and hypertension because of demonstrated CV disease and kidney benefits. A regimen including an ACE inhibitor with a thiazide-type diuretic is considered first-line in recurrent stroke prevention base on proven benefits from the PROGRESS trial showing reduced risk of secondary stroke.[32] In combination with β-blocker therapy, evidence shows that ACE inhibitors further reduce CV risk in coronary disease and in patients post-MI.[57,59,61,62] These benefits of ACE inhibitors occur in patients with atherosclerotic vascular disease even in the absence of left ventricular dysfunction and have the potential to reduce the development of new-onset type 2 diabetes.[94]

Most ACE inhibitors can be dosed once daily in hypertension (Table 19–5). In some patients, especially when higher doses are used, twice daily dosing is needed to maintain 24-hour effects with enalapril, benazepril, moexipril, quinapril and ramipril.

ACE inhibitors are well tolerated,[95] but are not absent of side effects. ACE inhibitors decrease aldosterone and can increase potassium serum concentrations. While this increase is usually small, hyperkalemia is possible. Patients with chronic kidney disease or those on concomitant potassium supplements, potassium-sparing diuretics, ARBs, or a direct renin inhibitor are at risk for hyperkalemia. Judicious monitoring of serum potassium and creatinine values within 4 weeks of starting or increasing the dose of an ACE inhibitor can often identify these abnormalities early before they evolve into serious adverse events.

The most worrisome adverse effect of ACE inhibitor is acute kidney failure. This serious adverse effect is rare, occurring in less than 1% of patients. Preexisting kidney disease increases the risk of this side effect. Bilateral renal artery stenosis or unilateral stenosis of a solitary functioning kidney render patients dependent on the vasoconstrictive effect of angiotensin II on the efferent arteriole of the kidney, thus explaining why these patients are particularly susceptible to acute kidney failure from ACE inhibitors. Slow titration of the ACE inhibitor dose and judicious kidney function monitoring can minimize risk and allow for early detection of those with renal artery stenosis.

It is important to note that GFR does decrease somewhat in patients when started on ACE inhibitors or ARBs.[64] This is attributed to the inhibition of angiotensin II vasoconstriction on the efferent arteriole. This decrease in GFR often increases serum creatinine, and small increases should be anticipated when monitoring patients on ACE inhibitors. Modest elevations of either ≤35% (for baseline creatinine values less than or equal to 3 mg/dL) or absolute increases less than 1 mg/dL do not warrant changes.[64] If larger increases occur, ACE inhibitor therapy should be stopped or the dose reduced.

Angioedema is a serious potential complication of ACE inhibitor therapy. It occurs in less than 1% of the population, and it is more likely in African-Americans and smokers. Symptoms include lip and tongue swelling and possibly difficulty breathing. Drug withdrawal is appropriate for treating patients with angioedema. However, angioedema associated with laryngeal edema and/or pulmonary symptoms occasionally occurs and requires additional treatment with epinephrine, corticosteroids, antihistamines, and/or emergent intubations to support respiration. A history of angioedema, even if not from an ACE inhibitor, precludes use of another ACE inhibitor (it is a contraindication). Cross-reactivity between ACE inhibitors and ARBs does not appear to be a significant concern. The Telmisartan randomized assessment study in ACE intolerant subjects with cardiovascular disease (TRANSCEND) trial enrolled 75 patients with a history of ACE-inhibitor–induced angioedema, and randomized these patients to either placebo or ARB therapy.[96] There were no cases of repeat angioedema among these patients. These data suggest the cross-reactivity is very low. Hence, an ARB can be used in a patient with a history of ACE-inhibitor–induced angioedema when it is needed. However, clinicians should monitor for repeat occurrences, since idiopathic angioedema may still occur.

A persistent dry cough develops in up to 20% of patients treated with an ACE inhibitor. It is pharmacologically explained by the inhibition of bradykinin breakdown. This cough does not cause respiratory illness but is annoying to patients and can compromise

adherence. It should be clearly differentiated from a wet cough due to pulmonary edema, which may be a sign of uncontrolled heart failure versus an ACE-inhibitor–induced cough.

ACE inhibitors, as well as ARBs, are absolutely contraindicated in pregnancy.[1,78] Female patients of child-bearing age should be counseled regarding effective forms of birth control as ACE inhibitors have been associated with major congenital malformations when exposed in the first trimester and fetopathy (group of conditions that includes renal failure, renal dysplasia, hypotension, oligohydramnios, pulmonary hypotension, hypocalvaria, and death) has occurred when exposed in the second and third trimester.[78] Similar to diuretics, ACE inhibitors can increase lithium serum concentrations in patients on lithium therapy. Concurrent use of an ACE with a potassium sparing diuretic (including aldosterone antagonists), potassium supplements, an ARB, or a direct renin inhibitor may result in hyperkalemia.

Starting doses of ACE inhibitors should be low, with even lower doses for patients at risk for orthostatic hypotension or severe renal dysfunction (e.g., elderly, chronic kidney disease). Acute hypotension may occur at the onset of ACE inhibitor therapy. Patients who are sodium or volume depleted, in heart failure exacerbation, very elderly, or on concurrent vasodilators or diuretics are at high risk for this effect. It is important to start with half the normal dose of an ACE inhibitor for all patients with these risk factors and to use slow dose titration.

ARBs Angiotensin II is generated by two enzymatic pathways: the RAAS, which involves ACE, and an alternative pathway that uses other enzymes such as chymase (aka "tissue ACE"). ACE inhibitors inhibit only the effects of angiotensin II produced through the RAAS, whereas ARBs inhibit angiotensin II from all pathways. It is unclear how these differences affect tissue concentrations of ACE. ACE inhibitors only partially block the effects of angiotensin II, though the clinical significance of this is not known.

ARBs directly block the angiotensin II type 1 (AT_1) receptor that mediates the known effects of angiotensin II in humans: vasoconstriction, aldosterone release, sympathetic activation, antidiuretic hormone release, and constriction of the efferent arterioles of the glomerulus. They do not block the angiotensin II type 2 (AT_2) receptor. Therefore, beneficial effects of AT_2 receptor stimulation (vasodilatation, tissue repair, and inhibition of cell growth) remain intact when ARBs are used. Unlike ACE inhibitors, ARBs do not block the breakdown of bradykinin. Therefore, some of the beneficial effects of bradykinin, such as vasodilation, regression of myocyte hypertrophy and fibrosis, and increased levels of tissue plasminogen activator, are not present with ARB therapy.

ARB therapy has been directly compared to ACE inhibitor therapy in the management of hypertension.[97] The Ongoing Telmisartan Alone and in Combination with Ramipril Global End point Trial (ON-TARGET) was a double-blind trial that randomized 25,620 patients with hypertension to either ACE-inhibitor–based therapy, ARB-based therapy, or the combination of an ACE inhibitor with an ARB. The primary end point was a composite end point of CV death or hospitalization for heart failure. After a median follow-up of 56 months, there was no difference in the primary end point between any of the three treatment groups. Therefore, these data establish that the CV event lowering benefits of ARB therapy are similar to ACE inhibitor therapy in hypertension. Moreover, the combination of an ACE inhibitor with an ARB had no additional CV event lowering but was associated with a higher risk of side effects (renal dysfunction, hypotension). Therefore, there is no reason to use an ACE inhibitor with an ARB for the management of hypertension.

For patients with certain compelling indications, ARBs have outcome data showing long-term reductions in progression of target-organ damage. For patients with type 2 diabetes and nephropathy, progression of nephropathy has been shown to be significantly reduced with ARB therapy.[21] Some benefits appear to be independent of BP lowering, suggesting that the pharmacologic effects of ARBs on the efferent arteriole may result in attenuated progression of kidney disease. For patients with left ventricular dysfunction, the CHARM studies showed that ARB therapy reduces risk of hospitalization for heart failure when added to a stable regimen of a diuretic, ACE inhibitor, and β-blocker or as an alternative therapy in ACE intolerant patients.[55,56] Importantly, the Evaluation of Losartan in the Elderly (ELITE) studies have shown that losartan is not superior to captopril in left ventricular dysfunction when compared head-to-head.[53,54]

ARBs have been compared head-to-head with CCBs. The MOSES demonstrated that eprosartan reduced the occurrence of recurrent stroke greater than nitrendipine in patients with a past medical history of cerebrovascular disease.[71] Using nitrendipine was a reasonable comparator because the Syst-Eur had already demonstrated that nitrendipine reduces the occurrence of CV events, particularly stroke, in older patients with isolated systolic hypertension compared to placebo.[11] These data support the common notion that ARBs may have cerebroprotective effects that may explain CV event reductions.[98] Another outcome study, the Valsartan Antihypertensive Long-term Use Evaluation (VALUE) trial, showed that valsartan-based therapy is equivalent to amlodipine-based therapy for the primary composite outcome of first CV event in patients with hypertension and additional CV risk factors.[34] However, occurrence of certain components of the primary end point (stroke and MI) and new onset type 2 diabetes was lower in the valsartan group. Although patients treated with amlodipine had slightly lower mean BP values than valsartan treated patients, there was no difference in the primary end point.

The addition of low doses of a thiazide-type diuretic to an ARB or a CCB to an ARB significantly increases antihypertensive efficacy. Similar to ACE inhibitors, most ARBs have long enough half-lives to allow for once daily dosing. However, candesartan, eprosartan, losartan, and valsartan have the shortest half-lives and may require twice daily dosing for sustained BP lowering.

ARBs have the lowest incidence of side effects compared to other antihypertensive agents.[95] Because they do not affect bradykinin, they do not illicit a dry cough like ACE inhibitors. While these drugs have been referred to as "ACE inhibitors without the cough," pharmacologic differences highlight that they could have very different effects on vascular smooth muscle and myocardial tissue that can correlate to different effects on target-organ damage and CV risk reduction when compared with ACE inhibitors. It is possible that their effects may be superior to ACE inhibitors for patients with type 2 diabetic nephropathy but may be inferior to ACE inhibitors in patients with more advanced heart disease (e.g., heart failure, post-MI). Regardless, their role for patients with type 2 diabetic nephropathy is well established, and they also are very reasonable alternatives for patients requiring an ACE inhibitor but who experience an intolerable cough.

Like ACE inhibitors, ARBs may cause renal insufficiency, hyperkalemia, and orthostatic hypotension. The same precautions that apply to ACE inhibitors for patients with suspected bilateral renal artery stenosis, those on drugs that can raise potassium and those on drugs that increase risk of hypotension apply to ARBs. As discussed in the section "ACE Inhibitors, ARBs, and CCBs as First-Line Agents", patients with a history of ACE inhibitor angioedema can be treated with an ARB when needed.[96] ARBs should not be used in pregnancy.[78]

CCBs CCBs, both dihydropyridine CCBs and non-dihydropyridine CCBs, are first-line therapy options and are very effective antihypertensive agents.[1,2] They also have compelling indications in

coronary artery disease and in diabetes. However, with these compelling indications, they are in addition to, or in instead of, other first-line antihypertensive drug classes.

Contraction of cardiac and smooth muscle cells requires an increase in free intracellular calcium concentrations from the extracellular fluid. When cardiac or vascular smooth muscle is stimulated, voltage-sensitive channels in the cell membrane are opened, allowing calcium to enter the cells. The influx of extracellular calcium into the cell releases stored calcium from the sarcoplasmic reticulum. As intracellular free calcium concentration increases, it binds to a protein, calmodulin, which then activates myosin kinase enabling myosin to interact with actin to induce contraction. CCBs work by inhibiting influx of calcium across the cell membrane. There are two types of voltage-gated calcium channels: a high-voltage channel (L-type) and a low-voltage channel (T-type). Currently available CCBs only block the L-type channel, which leads to coronary and peripheral vasodilatation.

The two subclasses of CCBs, dihydropyridines and non-dihydropyridines (see Table 19–5), are pharmacologically very different from each other. Antihypertensive effectiveness is similar with both subclasses, but they differ somewhat in other pharmacodynamic effects. Non-dihydropyridines (verapamil and diltiazem) decrease heart rate and slow atrioventricular nodal conduction. Similar to β-blockers these drugs may also treat supraventricular tachyarrhythmias (e.g., atrial fibrillation). Verapamil produces negative inotropic and chronotropic effects that are responsible for its propensity to precipitate or cause systolic heart failure in high risk patients. Diltiazem also has these effects but to a lesser extent than verapamil. All CCBs (except amlodipine and felodipine) have negative inotropic effects. Dihydropyridines may cause a baroreceptor-mediated reflex tachycardia because of their potent peripheral vasodilating effects. This effect appears to be more pronounced with the first-generation dihydropyridines (e.g., nifedipine) and is significantly diminished with the newer agents (e.g., amlodipine) and when given in sustained release dosage forms. Dihydropyridines do not alter conduction through the atrioventricular node and thus are not effective agents in supraventricular tachyarrhythmias.

Dihydropyridine CCBs CCBs, both dihydropyridines and non-dihydropyridines, are as effective at lowering CV events as other first-line agents in most patients with hypertension. The dihydropyridine CCBs have been extensively studied. In ALLHAT there was no difference in the primary outcome between chlorthalidone and amlodipine, and only the secondary outcome of heart failure was higher with amlodipine.[31] A subgroup analysis of ALLHAT directly compared amlodipine to lisinopril and demonstrated that there was no difference in the primary outcome.[99] However, amlodipine was superior to lisinopril for BP control in blacks, and for stroke reduction in blacks and in women. There was a lower risk of heart failure in the lisinopril group. As discussed previously, the VALUE study also showed no difference between valsartan and amlodipine in the primary outcome of first CV event in high-risk patients.[34]

Dihydropyridine CCBs are very effective in older patients with isolated systolic hypertension. The Syst-Eur, a placebo-controlled trial, demonstrated that a long-acting dihydropyridine CCB reduced the risk of CV events markedly in isolated systolic hypertension.[11] A long-acting dihydropyridine CCB should be strongly considered as preferred add-on therapy when a thiazide-type diuretic is not controlling BP in a patient with isolated systolic hypertension and no other compelling indications.

Among dihydropyridines, short-acting nifedipine may rarely cause an increase in the frequency, intensity, and duration of angina in association with acute hypotension. This effect is most likely due to a reflex sympathetic stimulation and is likely obviated by using sustained-release formulations of nifedipine. For this reason, all other dihydropyridines have an intrinsically long half-life or are sustained-release formulations. Immediate-release nifedipine has been associated with an increased incidence of adverse CV effects, is not approved for treatment of hypertension, and should not be used to treat hypertension. Other side effects with dihydropyridines include dizziness, flushing, headache, gingival hyperplasia, peripheral edema, mood changes, and various gastrointestinal complaints. Side effects due to vasodilatation such as dizziness, flushing, headache, and peripheral edema occur more frequently with all dihydropyridines than with the non-dihydropyridines (i.e., verapamil, diltiazem) because they are less potent vasodilators.

Non-Dihydropyridine CCBs Diltiazem and verapamil can cause cardiac conduction abnormalities such as bradycardia or atrioventricular block. These problems occur mostly with high doses or when used for patients with preexisting abnormalities in the cardiac conduction system. Heart failure has been reported in otherwise healthy patients due to negative inotropic effects. Both drugs can cause anorexia, nausea, peripheral edema, and hypotension. Verapamil causes constipation in about 7% of patients. This side effect also occurs with diltiazem, but to a lesser extent.

Verapamil and to a lesser extent diltiazem, can cause drug interactions due to their ability to inhibit the cytochrome P450 3A4 isoenzyme system. This inhibition can increase serum concentrations of other drugs that are metabolized by this isoenzyme system (e.g., cyclosporine, digoxin, lovastatin, simvastatin, tacrolimus, theophylline). Verapamil and diltiazem should be given very cautiously with a β-blocker because there is an increased risk of heart block with these combinations. When a CCB is needed in combination with a β-blocker for BP lowering, a dihydropyridine should be selected because it will not increase risk of heart block. The hepatic metabolism of CCBs, especially felodipine, nicardipine, nifedipine, and nisoldipine may be inhibited by ingesting large quantities of grapefruit juice (greater than or equal to 1 qt daily).

Many different formulations of verapamil and diltiazem are currently available (see Table 19–5). Although certain sustained release verapamil and diltiazem products contain the same active drug (e.g., Calan SR and Verelan), they are usually not AB rated by the FDA as interchangeable on a milligram-per-milligram basis due to different biopharmaceutical release mechanisms. However, the clinical significance of these differences is likely negligible.

Two sustained-release verapamil products (Covera HS and Verelan PM) and one diltiazem product (Cardizem LA) are chronotherapeutically designed to target the circadian BP rhythm. These agents are primarily dosed in the evening (with the exception of Cardizem LA, which may be dosed in the morning or evening) so that drug is released during the early morning hours when BP first starts to increase. The rationale behind chronotherapy in hypertension is that blunting the early morning BP surge may result in greater reductions in CV events than conventional dosing of regular antihypertensive products in the morning. However, evidence from the Controlled ONset Verapamil Investigation of Cardiovascular End-points (CONVINCE) trial showed that chronotherapeutic verapamil was similar, but not better than, a thiazide-type diuretic–β-blocker-based regimen with respect to CV events.[29]

β-Blockers β-blockers have been used in several large outcome trials in hypertension. However, in most of these trials, a thiazide-type diuretic was the primary agent with a β-blocker added on for additional BP lowering. Moreover, as previously discussed, for patients with hypertension but without compelling indications, other primary agents (thiazide-type diuretics, ACE inhibitors, ARBs, and CCBs) should be used as the initial first-line agent before β-blockers. While this may be surprising to experienced clinicians, this recommendation is consistent with the 2007 AHA guidelines and the 2006 United Kingdom's National Institute for Health and

the Clinical Excellence guidelines.[2,43] It is based on meta-analyses that suggest β-blocker-based therapy may not reduce CV events as well as these other agents when used as the initial drug to treat patients with hypertension and without a compelling indication for a β-blocker.[44–47]

β-blockers are only considered appropriate first-line agents to treat specific compelling indications (post-MI, coronary artery disease). β-blockers are also evidenced-based as additional therapy for other compelling indications (left ventricular dysfunction and diabetes). Numerous trials have shown reduced CV risk when β-blockers are used following an MI, during an acute coronary syndrome, or in chronic stable angina. Although once contraindicated in heart failure, studies have shown that bisoprolol, carvedilol, and metoprolol succinate reduce mortality in patients with left ventricular dysfunction who are treated with a diuretic and ACE inhibitor.

Several mechanisms of action have been proposed for β-blockers, but none of them alone has been shown to be consistently associated with a reduction in arterial BP. β-blockers have negative chronotropic and inotropic cardiac effects that reduce CO, which explains some of the antihypertensive effect. However, CO falls equally for patients treated with β-blockers regardless of BP lowering. Additionally, β-blockers with ISA do not reduce CO, yet they lower BP and decrease peripheral resistance.

β-Adrenoceptors are also located on the surface membranes of juxtaglomerular cells, and β-blockers inhibit these receptors and thus the release of renin. However, there is a weak association between plasma renin and antihypertensive efficacy of β-blocker therapy. Some patients with low plasma renin concentrations do respond to β-blockers. Therefore, additional mechanisms must also account for the antihypertensive effect of β-blockers. However, the ability of β-blockers to reduce plasma renin and thus angiotensin II concentrations may play a major role in their ability to reduce CV risk.

There are important pharmacodynamic and pharmacokinetic differences among β-blockers, but all agents provide a similar degree of BP lowering. There are three pharmacodynamic properties of the β-blockers that differentiate this class: cardioselectivity, ISA, and membrane-stabilizing effects. β-blockers that possess a greater affinity for β_1-receptors than β_2-receptors are *cardioselective.*

β_1-Adrenoceptors and β_2-adrenoceptors are distributed throughout the body, but they concentrate differently in certain organs and tissues. There is a preponderance of β_1-receptors in the heart and kidney, and a preponderance of β_2-receptors in the lungs, liver, pancreas, and arteriolar smooth muscle. β_1-Receptor stimulation increases heart rate, contractility, and renin release. β_2-Receptor stimulation results in bronchodilation and vasodilatation. Cardioselective β-blockers are not likely to provoke bronchospasm and vasoconstriction. Insulin secretion and glycogenolysis are mediated by β_2-receptors. Blocking β_2-receptors may reduce these processes and cause hyperglycemia or blunt recovery from hypoglycemia.

Cardioselective β-blockers (e.g., atenolol, metoprolol, nebivolol) have clinically significant advantages over nonselective β-blockers (e.g., propranolol, nadolol), and are preferred when using a β-blocker to treat hypertension. Cardioselective agents are safer than nonselective agents for patients with asthma or diabetes that have a compelling indication for a β-blocker. However, cardioselectivity is a dose-dependent phenomenon; at higher doses, cardioselective agents lose their relative selectivity for β_1-receptors and block β_2-receptors as effectively as they block β_1-receptors. The dose at which cardioselectivity is lost varies from patient to patient.

Some β-blockers (e.g., acebutolol, pindolol) have ISA and act as partial β-receptor agonists. When they bind to the β-receptor, they stimulate it, but far less than a pure β-agonist. If sympathetic tone is low, as it is during resting states, β-receptors are partially stimulated by ISA β-blockers. Therefore, resting heart rate, CO, and peripheral blood flow are not reduced when these type of β-blockers are used. Theoretically, ISA agents would appear to have advantages over β-blockers in certain patients with heart failure or sinus bradycardia. Unfortunately, they do not appear to reduce CV events as well as other β-blockers. In fact, they may increase risk post-MI or in those with coronary artery disease. Thus, agents with ISA are rarely needed.

All β-blockers exert a *membrane-stabilizing action* on cardiac cells when large doses are given. This activity is needed when β-blockers are used as an antiarrhythmic agent.

Pharmacokinetic differences among β-blockers relate to first-pass metabolism, route of elimination, degree of being lipophilic, and serum half-lives. Propranolol and metoprolol undergo extensive first-pass metabolism, so the dose needed to attain β-blockade with either drug varies from patient to patient. Atenolol and nadolol are renally excreted. The dose of these agents may need to be reduced for patients with moderate to severe chronic kidney disease.

β-blockers, especially those with high lipophilic properties, penetrate the central nervous system and may cause other effects. Propranolol is the most lipophilic drug and atenolol is the least lipophilic. Therefore, higher brain concentrations of propranolol compared to atenolol are seen after equivalent doses are given. It is thought that higher lipophilicity is associated with more central nervous system side effects (dizziness, drowsiness). However, the lipophilic properties can provide better effects for non-CV conditions such as migraine headache prevention, essential tremor, and thyrotoxicosis. BP lowering is equal among β-blockers regardless of lipophilicity.

Most side effects of β-blockers are an extension of their ability to antagonize β-adrenoceptors. β-blockade in the myocardium can be associated with bradycardia, atrioventricular conduction abnormalities (e.g. second- or third-degree heart block), and the development of acute heart failure. The decreases in heart rate may actually benefit certain patients with atrial arrhythmias (atrial fibrillation, atrial flutter) and hypertension by both providing rate control and BP lowering. β-blockers usually only produce heart failure if they are used in high initial doses for patients with preexisting left ventricular dysfunction or if started in these patients during an acute heart failure exacerbation. Blocking β_2-receptors in arteriolar smooth muscle may cause cold extremities and may aggravate intermittent claudication or Raynaud phenomenon as a result of decreased peripheral blood flow. In addition, there is an increase of sympathetic tone during periods of hypoglycemia in patients with diabetes that may result in a significant increase in BP because of unopposed α-receptor-mediated vasoconstriction.

Abrupt cessation of β-blocker therapy can produce unstable angina, MI, or even death in patients with coronary disease. Abrupt cessation may also lead to rebound hypertension (a sudden increase in BP to or above pretreatment values). To avoid this, β-blockers should always be tapered gradually over 1 to 2 weeks before eventually discontinuing the drug. This acute withdrawal syndrome is believed to be secondary to progression of underlying coronary disease, hypersensitivity of β-adrenergic receptors due to up regulation, and increased physical activity after withdrawal of a drug that decreases myocardial oxygen requirements. For patients without coronary disease, abrupt discontinuation may present as tachycardia, sweating, and generalized malaise in addition to increased BP.

Like diuretics, β-blockers have been shown to increase serum cholesterol and glucose values, but these effects are transient and of little clinical significance. For patients with diabetes, the reduction in CV events was as great with β-blockers as with an ACE inhibitor in the United Kingdom Prospective Diabetes Study (UKPDS)[100] and far superior to placebo in the SHEP trial.[8] In the Glycemic Effects in Diabetes Mellitus: Carvedilol-Metoprolol Comparison in Hypertensives (GEMINI) trial, patients with diabetes and

hypertension who were randomized to metoprolol had an increase in hemoglobin A1C values, while patients randomized to carvedilol did not.[101] This suggests that mixed α and β-blocking effects of carvedilol may be preferential to metoprolol for patients with uncontrolled diabetes. However, differences in hemoglobin A1C values were too small to make this application clinically relevant in all patients with diabetes that need treatment with a β-blocker. Nebivolol is considered a third-generation β-blocker. Similar to carvedilol and labetalol, this β-blocker results in vasodilatation. However, carvedilol and labetalol cause vasodilatation because of their ability to block α-receptors, while nebivolol causes vasodilatation through release of nitric oxide. The long-term clinical benefits of the nitric oxide effects seen with nebivolol are currently unknown, but this might explain a lower risk of β-blocker associated fatigue, erectile dysfunction, and metabolic side effects (e.g., hyperglycemia) with this agent.

⓭ Alternative Agents The primary role of an alternative antihypertensive agent is to provide additional BP lowering in patients that are already treated with antihypertensive agents from a drug class proven to reduce hypertension associated CV events (diuretics, ACE inhibitors, ARBs, CCBs, and/or β-blockers).

***α_1-Blockers*[36]** Prazosin, terazosin, and doxazosin are selective α_1-receptor blockers. They work in the peripheral vasculature and inhibit the uptake of catecholamines in smooth muscle cells resulting in vasodilatation and BP lowering.

Doxazosin was one of the original treatment arms of the ALLHAT. However, it was stopped prematurely when statistically more secondary end points of stroke, heart failure, and CV events were seen with doxazosin compared with chlorthalidone.[36] There were no differences in the primary end point of fatal coronary heart disease and nonfatal MI. These data suggest that thiazide-type diuretics are superior to α_1-blockers in preventing CV events in patients with hypertension. Therefore, α_1-blockers are alternative agents that should be used in combination with first-line antihypertensive agents.

α_1-Blockers can provide symptomatic benefits in men with benign prostatic hypertrophy. These agents block postsynaptic α_1-adrenergic receptors located on the prostate capsule, causing relaxation and decreased resistance to urinary outflow. However, when used to lower BP, they should only be in addition to other first-line antihypertensive agents.

A potentially severe side effect of α_1-blockers is a "first-dose" phenomenon that is characterized by transient dizziness or faintness, palpitations, and even syncope within 1 to 3 hours of the first dose. This adverse reaction can also happen after dose increases. These episodes are accompanied by orthostatic hypotension and can be obviated by taking the first dose and subsequent first increased doses at bedtime. Because orthostatic hypotension and dizziness may persist with chronic administration, these agents should be used very cautiously in elderly patients. Even though antihypertensive effects are achieved through a peripheral α_1-receptor antagonism, these agents cross the blood–brain barrier and may cause central nervous system side effects such as lassitude, vivid dreams, and depression. α_1-Blockers also may cause priapism. Sodium and water retention can occur with higher doses, and sometimes even with chronic administration of low doses. Therefore, these agents are most effective when given in combination with a diuretic to maintain antihypertensive efficacy and minimize potential edema.

***Aliskiren*[102,103]** Aliskiren is the first oral agent within a new antihypertensive drug class that directly inhibits renin.[102] This drug blocks the RAAS at its point of activation, which results in reduced plasma renin activity and BP lowering. It has a 24-hour half-life, is primarily eliminated through biliary excretion unchanged, and provides 24-hour antihypertensive effects with once daily dosing.

The exact role of this drug class in the management of hypertension is unclear. Aliskiren is approved as monotherapy or in combination therapy. However, because of the lack of long-term studies evaluating CV event reduction and significant drug cost compared to older generic agents with outcome data; it should clearly be used as an alternative therapy for the treatment of hypertension. The Aliskiren in the Evaluation of Proteinuria in Diabetes (AVOID) trial demonstrated that the combination of aliskiren with losartan resulted in a reduction in proteinuria compared to losartan alone in patients with type 2 diabetes.[104] This may be a future role for this particular drug class after more clinical trials have been completed. Aliskiren is effective in lowering BP when used in combination with thiazide-type diuretics, ACE inhibitors, ARBs, or a CCB; however, its effectiveness in combination with maximum doses of ACE inhibitor, ARB, or other CCBs has not been adequately studied.

Many of the cautions and adverse effects seen with ACE inhibitors and ARBs apply to direct renin inhibitors (e.g., aliskiren). Aliskiren should never be used in pregnancy due to the known teratogenic effects of using other drugs that block the RAAS system. Angioedema has also been reported for patients treated with aliskiren. Increases in serum creatinine and serum potassium values have been observed. The mechanisms of these adverse effects are likely similar to those with ACE inhibitors and ARBs. It is reasonable to utilize similar monitoring strategies by measuring serum creatinine and serum potassium in patients treated with aliskiren. This is particularly important for patients treated with the combination of aliskiren and an ACE inhibitor or an ARB who are at higher risk for hyperkalemia (e.g., patients with diabetes and chronic kidney disease).

Central α_2-Agonists Clonidine, guanabenz, guanfacine, and methyldopa lower BP primarily by stimulating α_2-adrenergic receptors in the brain. This stimulation reduces sympathetic outflow from the vasomotor center in the brain and increases vagal tone. It is also believed that peripheral stimulation of presynaptic α_2-receptors may further reduce sympathetic tone. Reduced sympathetic activity together with enhanced parasympathetic activity can decrease heart rate, CO, TPR, plasma renin activity, and baroreceptor reflexes. Clonidine is often used in resistant hypertension, and methyldopa is a first-line agent for pregnancy-induced hypertension.

Chronic use of centrally acting α_2-agonists results in sodium and water retention, which is most prominent with methyldopa. Low doses of clonidine (and guanfacine or guanabenz) can be used to treat hypertension without the addition of a diuretic. However, methyldopa should be given in combination with a diuretic to avoid the blunting of antihypertensive effect that happens with prolonged use when used to treat chronic hypertension (not necessary in pregnancy induced hypertension). Sedation and dry mouth are common anticholinergic side effects that typically improve with chronic use of low doses, but they are more troublesome in the elderly. As with other centrally acting antihypertensives, depression can occur, especially with high doses. The incidence of orthostatic hypotension and dizziness is higher than with other antihypertensive agents, so they should be used very cautiously in the elderly. Lastly, clonidine has a relatively high incidence of anticholinergic side effects (sedation, dry mouth, constipation, urinary retention and blurred vision). Thus, it should generally be avoided for chronic antihypertensive therapy in the elderly.

Abrupt cessation of central α_2-agonists may lead to rebound hypertension. This effect is thought to be secondary to a compensatory increase in norepinephrine release after abrupt discontinuation. In addition, other effects such as nervousness, agitation, headache, and tremor can also occur, which may be exacerbated by concomitant β-blocker use, particularly with clonidine. Thus, if clonidine is to be discontinued it should be tapered. For patients who are receiving concomitant β-blocker therapy, the β-blocker

should be gradually discontinued first several days before gradual discontinuation of clonidine.

Methyldopa can cause hepatitis or hemolytic anemia, although this is rare. Transient elevations in serum hepatic transaminases are occasionally seen with methyldopa therapy but are clinically irrelevant unless they are greater than 3 times the upper limit or normal. Methyldopa should be quickly discontinued if persistent increases in serum hepatic transaminases or alkaline phosphatase are detected because this may indicate the onset of fulminant life threatening hepatitis. A Coombs-positive hemolytic anemia occurs in less than 1% of patients receiving methyldopa, although 20% exhibit a positive direct Coombs test without anemia. For these reasons, methyldopa has limited use in routine management of hypertension, except in pregnancy.

Reserpine Reserpine lowers BP by depleting norepinephrine from sympathetic nerve endings and blocking transport of norepinephrine into its storage granules. Norepinephrine release into the synapse following nerve stimulation is reduced and results in reduced sympathetic tone, peripheral vascular resistance, and BP. Reserpine also depletes catecholamines in the brain and the myocardium, which may lead to sedation, depression, and decreased CO.

Reserpine has a slow onset of action and long half-life that allows for once daily dosing. However, it may take 2 to 6 weeks before the maximal antihypertensive effect is seen. Because reserpine can cause significant sodium and water retention, it should be given in combination with a diuretic (preferably a thiazide). Reserpine's strong inhibition of sympathetic activity results in increased parasympathetic activity. This effect explains why side effects such as nasal stuffiness, increased gastric acid secretion, diarrhea, and bradycardia can occur. Depression has been reported, which is a consequence of central nervous system depletion of catecholamines and serotonin. The initial reports of depression with reserpine were in the 1950s and are not consistent with current definitions of depression. Regardless, reserpine-induced depression is dose related. Moreover, very high doses (above 1 mg daily) were frequently used in the 1950s, resulting in more depression. When reserpine is dosed between 0.05 and 0.25 mg daily (recommended doses), the rate of depression is equal to that seen with β-blockers, diuretics, or placebo.[8]

Reserpine was used as a third-line agent in many of the landmark clinical trials that have documented the benefit in treating hypertension, including the Veterans Administration Cooperative trials and the SHEP trial.[8] An analysis of the SHEP data found that reserpine was very well tolerated and that the combination of a thiazide-type diuretic and reserpine is very effective at lowering BP.

Direct Arterial Vasodilators Hydralazine and minoxidil directly relax arteriolar smooth muscle resulting in vasodilatation and BP lowering. They exert little to no venous vasodilatation. Both agents cause potent reductions in perfusion pressure that activates the baroreceptor reflexes. Activation of baroreceptors results in a compensatory increase in sympathetic outflow, which leads to an increase in heart rate, CO, and renin release. Consequently, tachyphylaxis can develop resulting in a loss of hypotensive effect with continued use. This compensatory baroreceptor response can be counteracted by concurrent use of a β-blocker.

All patients receiving hydralazine or minoxidil long-term for hypertension should first receive both a diuretic and a β-blocker. Direct arterial vasodilators can precipitate angina in patients with underlying coronary disease unless the baroreceptor reflex mechanism is completely blocked with a β-blocker. Non-dihydropyridine CCBs can be used as an alternative to β-blockers in these patients, but a β-blocker is preferred. The side effect of sodium and water retention is significant but is minimized by using a diuretic concomitantly.

One side effect unique to hydralazine is a dose-dependent drug-induced lupus-like syndrome. Hydralazine is eliminated by hepatic *N*-acetyltransferase. This enzyme displays genetic polymorphism, and "slow acetylators" are especially prone to develop drug-induced lupus with hydralazine. This syndrome is more common in women and is reversible upon discontinuation. Drug-induced lupus may be avoided by using less than 200 mg of hydralazine daily. Because of side effects, hydralazine has limited clinical use for chronic management of hypertension. However, it is especially useful for patients with severe chronic kidney disease and in kidney failure on hemodialysis.

Minoxidil is a more potent vasodilator than hydralazine. Therefore, the compensatory increases in heart rate, CO, renin release, and sodium retention are even more dramatic. Sodium and water retention can be so severe with minoxidil that heart failure can be precipitated. It is even more important to co-administer a β-blocker and a diuretic with minoxidil. A loop diuretic is often more effective than a thiazide in patients treated with minoxidil. A troublesome side effect of minoxidil is hypertrichosis (hirsutism), presenting as increased hair growth on the face, arms, back, and chest. This usually ceases when the drug is discontinued. Other minoxidil side effects include pericardial effusion and a nonspecific T-wave change on the electrocardiogram. Minoxidil is reserved for very difficult to control hypertension and for patients requiring hydralazine that experience drug-induced lupus.

PHARMACOECONOMIC CONSIDERATIONS

The cost of effectively treating hypertension is substantial. However, these costs are offset by savings that would be realized by reducing CV morbidity and mortality. Cost related to treating target-organ damage (e.g., MI, end-stage kidney failure) can drastically increase healthcare costs. The cost per life-year saved from treating hypertension has been estimated to be $40,000 for younger adults and even less for older adults.[105] Treatments that cost less than $50,000 per life-year saved generally are considered favorable by health economists.

Antihypertensive drug costs are a major portion of the total cost of hypertensive care. First-line drug classes recommended by the JNC7 and AHA guidelines, such as diuretics, ACE-inhibitors, and CCBs, are predominantly generic.[1,2] Using these agents to treat hypertension result in lower drug acquisition costs. There are even multiple generic fixed-dose combinations of these agents. A comparative analysis of 133,624 patients with hypertension aged 65 and older from a state prescription drug assistance program demonstrated that 40% of patients were prescribed pharmacotherapy that was not necessarily according to JNC7 guidelines recommendations.[106] If these 40% had drug therapy modifications made to follow evidence-based treatment, a reduction in costs of $11.6 million would have been realized in the 2001 calendar year based on discounted prices. This was projected to increase to $20.5 million using usual Medicaid pricing limits.

Other factors contribute to the overall cost of treating hypertension. Supplemental drugs, laboratory tests, clinic visits, and costs to treat complications of hypertension (e.g., CV events) can be staggering. A cost-minimization analysis found that 86 middle-aged or 29 elderly patients with hypertension would need to be treated to prevent one MI, stroke, or death.[107]

It is crucial to identify ways to control the cost of care without increasing the morbidity and mortality associated with uncontrolled hypertension. Using evidence-based pharmacotherapy will save costs. Thiazide-type diuretics, ACE inhibitors, and CCBs are first-line treatment options in most patients without compelling indications and are very inexpensive. Even the ARBs have one generic option (losartan, although more are expected in 2012). Just utilizing generic agents, either as monotherapy or in combination,

is appropriate under most circumstances in hypertension management. Brand name drugs should also be used when needed. However, considerations to implement once daily options, and even fixed-dose combination options that are economical should be considered.

Team-Based Collaborative Care

Team-based care for patients with hypertension is a proven strategy that improves goal BP attainment rates.[108] These patient care models are intraprofessional models of disease state management that utilize physicians, pharmacists, nurses, and other healthcare professionals. With the advent of healthcare reform, such approaches to chronic diseases are being viewed as high-quality and cost-effective improvement modalities. Within these models, pharmacists have been proven to be an effective component of these team-based models both in ambulatory clinic settings[109] and in community pharmacist settings.[110] In addition to optimizing selection and implementation of antihypertensive drug therapy, clinical interventions by pharmacists have been proven to reduce risk of adverse drug events and medication errors in ambulatory patients with CV disease.[111]

EVALUATION OF THERAPEUTIC OUTCOMES

MONITORING THE PHARMACOTHERAPY PLAN

Routine ongoing monitoring to assess disease progression, the desired effects of antihypertensive therapy (efficacy, including BP goal attainment), and undesired adverse side effects (toxicity) is needed in all patients treated with antihypertensive drug therapy.

Disease Progression

Patients should be monitored for signs and symptoms of progressive hypertension-associated target-organ disease. A careful history for ischemic chest pain (or pressure), palpitations, dizziness, dyspnea, orthopnea, headache, sudden change in vision, one-sided weakness, slurred speech, and loss of balance should be taken to assess the presence of CV and cerebrovascular hypertensive complications. Other clinical monitoring parameters that may be used to assess target-organ disease include funduscopic changes on eye exam, left ventricular hypertrophy on electrocardiogram, proteinuria, and changes in kidney function. These parameters should be monitored periodically because any sign of deterioration requires immediate assessment and follow-up.

Efficacy

The most important strategy to prevent CV morbidity and mortality in hypertension is BP control to goal values (see Box 19–2). Routine goal BP values should be attained in elderly patients and in those with isolated systolic hypertension, but actual BP lowering can occur at a very gradual pace over a period of several months to avoid orthostatic hypotension. Modifying other CV risk factors (e.g., smoking, dyslipidemia, and diabetes) is also important.

Clinic-based BP monitoring remains the standard for managing hypertension. BP response should be evaluated 2 to 4 weeks after initiating or making changes in therapy. With some agents, monitoring BP 4 to 6 weeks later may better represent steady state BP values (e.g., thiazide-type diuretics, reserpine). Once goal BP values are attained, assuming no signs or symptoms of acute target-organ disease are present, BP monitoring can be done every 3 to 6 months. More frequent evaluations are required for patients with a history of poor control, nonadherence, progressive target-organ damage, or symptoms of adverse drug effects.

TABLE 19-8 Select Monitoring for Antihypertensive Pharmacotherapy

Class	Parameters
Diuretics	Blood pressure; BUN/serum creatinine; serum electrolytes (potassium, magnesium, sodium); uric acid (for thiazides)
Aldosterone antagonists	Blood pressure; BUN/serum creatinine; serum potassium
ACE inhibitors	Blood pressure; BUN/serum creatinine; serum potassium
ARBs	Blood pressure; BUN/serum creatinine; serum potassium
Calcium channel blockers	Blood pressure; heart rate
β-blockers	Blood pressure; heart rate

Self-measurements of BP or automated ambulatory BP monitoring can be useful clinically to establish effective 24-hour control. This type of monitoring may become the standard of care in the future, but currently, ambulatory BP monitoring is used in select situations such as suspected white coat hypertension.[14] If patients are measuring their BP at home, it is important that they measure during the early morning hours for most days and then at different times of the day on alternative days of the week.

Toxicity

Patients should be monitored routinely for adverse drug effects. The most common side effects associated with each class of antihypertensive agents were discussed in the Individual Antihypertensive Agents section, and laboratory parameters for primary agents are listed in Table 19–8. Laboratory monitoring should typically occur 2 to 4 weeks after starting a new agent or dose increase, and then every 6 to 12 months in stable patients. Additional monitoring may be needed for other concomitant diseases if present (e.g., diabetes, dyslipidemia, gout). Moreover, patients treated with an aldosterone antagonist (eplerenone or spironolactone) should have potassium concentrations and kidney function assessed within 3 days of initiation and again at 1 week to detect potential hyperkalemia.[48] The occurrence of an adverse drug event may require dosage reduction or substitution with an alternative antihypertensive agent.

Adherence

Lack of persistence with hypertension treatment is a major problem in the United States and is associated with significant increases in costs due to development of complications. Since hypertension is a relatively asymptomatic disease, poor adherence is frequent, particularly in patients newly treated. It has been estimated that up to 50% of patients with newly diagnosed hypertension are continuing treatment at 1 year.[112] It has also been demonstrated that long-term risk of CV events is significantly reduced when newly diagnosed patients are adherent with their antihypertensive drug therapy.[113] Therefore, it is imperative to assess patient adherence on a regular basis.

Identification of nonadherence should be followed up with appropriate patient education, counseling, and intervention. Once-daily regimens are preferred in most patients to improve adherence. Although some may believe that aggressive treatment may negatively impact quality of life and thus adherence, several studies have found that most patients actually feel better once their BP is controlled. Patients on antihypertensive therapy should be questioned periodically about changes in their general health perception, energy level, physical functioning, and overall satisfaction with treatment. Lifestyle modifications should always be recommended to provide additional BP lowering and other potential health

benefits. Persistence with lifestyle modifications should be continually encouraged for patients engaging in such endeavors.

COMBINATION THERAPY

14 Initial therapy with a combination of two drugs is highly recommended for patients with Stage 2 hypertension and is an option for treating patients with Stage 1 hypertension where goal achievement may be difficult (e.g., those with BP goals of less than 130/80 mm Hg, African-Americans). Using a fixed-dose combination product is an option for these types of patients and has been shown to improve adherence.[114] Initial two-drug combination therapy may also be appropriate for patients with multiple compelling indications for different antihypertensive agents. Moreover, combination therapy is often needed to control BP in patients that are already on drug therapy and most patients require two or more agents.[1,42,64,73]

The Avoiding Cardiovascular Events Through Combination Therapy for Patients Living with Systolic Hypertension (ACCOMPLISH) Trial

Long-term safety and efficacy of initial two drug therapy for hypertension has been evaluated in the ACCOMPLISH trial.[115] This was a prospective, randomized, double-blind trial in 11,506 patients with hypertension and other CV risk factors. All of these patients either had stage 2 hypertension or were on antihypertensive drug therapy upon enrollment. Patients were randomized to receive either benazepril-with-hydrochlorothiazide or benazepril-with-amlodipine as initial drug therapy. Treatment was titrated to a goal BP of less than 140/90 mm Hg for most patients and less than 130/80 mm Hg for patients with diabetes or chronic kidney disease.

The trial was terminated early after a mean of only 36 months because the incidence of CV events was 20% lower in the benazepril-with-amlodipine group compared with the benazepril-with-hydrochlorothiazide group. What is most important for clinical practice is that this trial established that initial therapy, as is recommended in the JNC7 and AHA guidelines, was safe and highly effective in lowering BP. Mean BP measurements were 132/73 mm Hg and 133/74 mm Hg in the benazepril-with-amlodipine and the benazepril-with-hydrochlorothiazide groups, respectively. However, rates of attaining a BP of less than 140/90 mm Hg were 75.4% and 72.4% (benazepril with amlodipine and benazepril with hydrochlorothiazide, respectively). These goal attainment rates are higher than in any other long-term prospective study and are higher than what is seen in clinical practice.

The ACCOMPLISH trial established initial two-drug antihypertensive therapy as an evidence-based strategy to treat hypertension. Clinicians should consider this study as positive justification for implementing initial two-drug therapy antihypertensive regimens in appropriate patients.

CLINICAL CONTROVERSY

What is the most effective two-drug combination for reducing CV events?

The ACCOMPLISH trial demonstrated that the combination of an ACE inhibitor with a dihydropyridine CCB was more effective in reducing risk of CV events than the combination of an ACE inhibitor with a thiazide-type diuretic.[115] However, thiazide-type diuretics are very effective at lowering BP, especially when used in combination with other agents, and have been traditionally viewed as the most appropriate second drug (if not used as the first drug) to treat hypertension.[88] Therefore, the most ideal two-drug combination for the treatment of hypertension is debatable.

Optimal Use of Combination Therapy

Clinicians should anticipate the need for three drugs to control BP in most patients when an aggressive BP goal of less than 130/80 mm Hg is targeted.[64] Using low-dose combinations also provides greater reductions in BP compared to high doses of single agents, with fewer drug-related side effects.[95] Contrary to popular myth, appropriately increasing the number of antihypertensive medications to attain goal BP values does not increase the risk of adverse effects.[116] Ideal combinations include two drugs with discretely different mechanisms of action that are supported by evidence demonstrating the ability to lower CV events.

Combination regimens for hypertension that include a diuretic, preferably a thiazide-type, are inexpensive and effective in lowering BP.[87,88] Diuretics, when combined with several agents (especially an ACE inhibitor, ARB, or β-blocker), can result in additive antihypertensive effects that are independent of reversing fluid retention. These fixed dose products are also readily available. BP lowering from certain antihypertensive agents can activate the RAAS as a compensatory mechanism to counteract BP changes and can regulate fluid loss. Most alternative antihypertensive agents (i.e., reserpine, arterial vasodilators, and centrally acting agents) need to be given with a diuretic to avoid sodium and water retention.

Some combinations either are less effective in lowering BP or are not effective long term in treating hypertension. As previously discussed, the ON-TARGET trial demonstrated that the use of an ACE inhibitor with an ARB in the management of hypertension results in no additional reduction in incidence of CV events.[97] Moreover, this combination results in a higher risk of adverse events. This combination should not be used for the purpose of managing hypertension. Other combinations such as a thiazide-diuretic with a potassium sparing agent, both of which appear to have overlapping mechanisms of action, should be implemented primarily to minimize side effects. The combination of two CCBs, a dihydropyridine with a non-dihydropyridine, might provide additional BP lowering[117,118] but has limited use in the routine management of patients with hypertension, perhaps for patient with diabetes.[64] Under no circumstance should two drugs from the same exact class of medications (e.g., two β-blockers, two ACE inhibitors) be used to treat hypertension.

Fixed-Dose Combination Products Many fixed-dose combination products are commercially available, and some are generic (see Table 19–9). Most of these products contain a thiazide-type diuretic and have multiple dose strengths available. Individual dose titration is more complicated with fixed-dose combination products, but this strategy can reduce the number of daily tablets/capsules and can simplify regimens to improve adherence by decreasing pill burden.[114] This alone may increase the likelihood of achieving or maintaining goal BP values. Depending on the product, some may be less expensive to patients and to health systems. Nonadherence rates are 24% lower when fixed-dose combination products are used to treat hypertension compared to using free drug components (separate pills) to treat hypertension.[119]

RESISTANT HYPERTENSION

15 Resistant hypertension is defined as patients who are uncontrolled (failure to achieve goal BP of <140/90 mm Hg, or lower when indicated) with the use of three or more drugs.[120] Ideally, these should be patients who are adhering to full doses of an appropriate three-drug regimen that includes a diuretic.[1] This also includes patients who are controlled but require the use of four or more mediations.[120] Patients with newly diagnosed hypertension or who are not receiving drug therapy should not be considered to have resistant hypertension.[121] Difficult-to-control hypertension is

TABLE 19-9 Fixed-Dose Combination Products

Combination	Drugs (Brand Name)	Strengths (mg/mg)	Daily Frequency
ACE inhibitor with a thiazide-type diuretic	Benazepril/hydrochlorothiazide (Lotensin HCT)	5/6.25, 10/12.5, 20/12.5, 20/25	1
	Captopril/hydrochlorothiazide (Capozide)	25/15, 25/25, 50/15, 50/25	1 to 3
	Enalapril/hydrochlorothiazide (Vaseretic)	5/12.5, 10/25	1
	Lisinopril/hydrochlorothiazide (Prinizide, Zestoretic)	10/12.5, 20/12.5, 20/25	1
	Moexipril/hydrochlorothiazide (Uniretic)	7.5/12.5, 15/25	1 or 2
	Quinapril/hydrochlorothiazide (Accuretic)	10/12.5, 20/12.5, 20/25	1
ARB with a thiazide-type diuretic	Candesartan/hydrochlorothiazide (Atacand HCT)	16/12.5, 32/12.5	1
	Eprosartan/hydrochlorothiazide (Teveten HCT)	600/12.5, 600/25	1
	Irbesartan/hydrochlorothiazide (Avalide)	75/12.5, 150/12.5, 300/12.5	1
	Losartan/hydrochlorothiazide (Hyzaar)	50/12.5, 100/25	1
	Olmesartan/hydrochlorothiazide (Benicar HCT)	20/12.5, 40/12.5, 40/25	1
	Telmisartan/hydrochlorothiazide (Micardis HCT)	40/12.5, 80/12.5	1
	Valsartan/hydrochlorothiazide (Diovan HCT)	80/12.5, 160/12.5	1
β-blocker with a thiazide-type diuretic	Atenolol/chlorthalidone (Tenoretic)	50/25, 100/25	1
	Bisoprolol/hydrochlorothiazide (Ziac)	2.5/6.25, 5/6.25, 10/6.25	1
	Propranolol/hydrochlorothiazide (Inderide)	40/25, 80/25	2
	Propranolol LA/hydrochlorothiazide (Inderide LA)	80/50, 120/50, 160/50	1
	Metoprolol/hydrochlorothiazide (Lopressor HCT)	50/25, 100/25	1 or 2
	Nadolol/bendroflumethazide (Corzide)	40/5, 80/5	1
	Timolol/hydrochlorothiazide (Timolide)	10/25	1 or 2
ACE inhibitor with CCB	Amlodipine/benazepril (Lotrel)	2.5/10, 5/10, 10/20	1
	Enalapril/felodipine (Lexxel)	5/5	1
	Trandolapril/verapamil (Tarka)	2/180, 1/240, 2/240, 4/240	1 or 2
ARB with CCB	Amlodipine/olmesartan (AZOR)	5/20, 10/20, 5/40, 10/40	1
	Telmisartan/amlodipine (Twynsta)	40/5, 40/10, 80/5, 80/10	1
	Valsartan/amlodipine (Exforge)	5/160, 10/160, 5/320,10/320	1
ARB with direct renin inhibitor	Aliskiren/valsartan (Valturna)	150/160, 300/320	1
Direct renin inhibitor with thiazide-type diuretic	Aliskiren/hydrochlorothiazide (Tekturna HCT)	150/12.5, 150/25, 300/12.5, 300/25	1
ARB with CCB with a thiazide-type diuretic	Amlodipine/valsartan/hydrochlorothiazide (Exforge HCT)	5/160/12.5, 5/160/25, 10/160/12.5, 10/160/25, 10/320/25	1
	Olmesartan, amlodipine, hydrochlorothiazide (Tribenzor)	20/5/12.5, 40/5/12.5, 40/5/25, 40/10/12.5, 40/10/25	1

persistently elevated BP despite treatment with two or three drugs that does not meet the criteria for resistant hypertension (e.g., maximum doses that include a diuretic).

Several causes of resistant hypertension are listed in Table 19–10. Volume overload is a common cause, thus highlighting the importance of diuretic therapy in the management of hypertension. Pseudoresistance should also be ruled out by assuring adherence with prescribed therapy and possibly use of home BP measurements (by using a self-monitoring device or 24-hour ABP monitor).[120] Patients should be closely evaluated to see if any of these causes can be reversed.

Treatment of patients with resistant hypertension should ultimately follow the principle of drug therapy selection from the JNC7 and AHA guidelines. Compelling indications, if present, should guide selection assuming these patients are on a diuretic.

TABLE 19-10 Causes of Resistant Hypertension

Improper BP measurement
Volume overload:
- Excess sodium intake
- Volume retention from kidney disease
- Inadequate diuretic therapy

Drug-induced or other causes:
- Nonadherence
- Inadequate doses
- Agents listed in Table 19–1

Associated conditions:
- Obesity, excess alcohol intake

Secondary hypertension

However, there are treatment philosophies that are germane to the management of resistant hypertension: (1) assuring adequate diuretic therapy, (2) appropriate use of combination therapies, and (3) using alternative antihypertensive agents when needed.[120]

Assuring Appropriate Diuretic Therapy

Diuretics have a large role in the pharmacotherapy of resistant hypertension. Thiazide-type diuretics are the mainstay of treatment, but chlorthalidone should be preferentially used instead of hydrochlorothiazide for patients with resistant hypertension because it is more potent on a milligram-per-milligram basis.[87,120] Clinicians should identify that chlorthalidone therapy, like all thiazide-type diuretics, has dose-dependent metabolic side effects (hypokalemia and hyperglycemia) and that appropriate monitoring should be implemented. An aldosterone antagonist (e.g., spironolactone) is also very effective as an add-on agent.[120] Evolving data indicate that many patients with resistant hypertension have some degree of underlying hyperaldosteronism, emphasizing the role of adding an aldosterone antagonist. Clinicians should consider using a loop diuretic, even in place of a thiazide-type diuretic, for patients with resistant hypertension that have very compromised kidney function (estimated GFR less than 30 mL/min/1.73 m^2). Torsemide can be dosed once daily while furosemide must be dosed twice daily or three times daily.

HYPERTENSIVE URGENCIES AND EMERGENCIES[1,6]

Hypertensive urgencies and emergencies both are characterized by the presence of very elevated BP, typically greater than 180/120 mm Hg. However, the need for urgent or emergent antihypertensive

therapy must be determined based on the presence of acute or immediately progressing target-organ injury, not elevated BP alone. Urgencies are not associated with acute or immediately progressing target-organ injury, while emergencies are. Examples of acute target-organ injury include encephalopathy, intracranial hemorrhage, acute left ventricular failure with pulmonary edema, dissecting aortic aneurysm, unstable angina, and eclampsia or severe hypertension during pregnancy.

Hypertensive Urgency

16 A common error with hypertensive urgency is overly aggressive antihypertensive therapy. This treatment has likely been perpetrated by the classification terminology "urgency." Hypertensive urgencies are ideally managed by adjusting maintenance therapy, by adding a new antihypertensive, and/or by increasing the dose of a present medication. This is the preferred approach to these patients as it provides a more gradual reduction in BP. Very rapid reductions in BP to goal values should be discouraged due to potential risks. Because autoregulation of blood flow in patients with hypertension occurs at a much higher range of pressure than in normotensive persons, the inherent risks of reducing BP too precipitously include cerebrovascular accidents, MI, and acute kidney failure. Hypertensive urgency requires BP reductions with oral antihypertensive agents to stage 1 values over a period of several hours to several days. All patients with hypertensive urgency should be reevaluated within and no later than 7 days (preferably after 1 to 3 days).

Acute administration of a short-acting oral antihypertensive (e.g., captopril, clonidine, or labetalol) followed by careful observation for several hours to assure a gradual reduction in BP is an option for hypertensive urgency. However, there are no data supporting this approach as being absolutely needed. Oral captopril is one of the agents of choice and can be used in doses of 25 to 50 mg at 1- to 2-hour intervals. The onset of action of oral captopril is 15 to 30 minutes, and a marked fall in BP is unlikely to occur if no hypotensive response is observed within 30 to 60 minutes. For patients with hypertensive rebound following withdrawal of clonidine, 0.2 mg can be given initially, followed by 0.2 mg hourly until the DBP falls below 110 mm Hg or a total of 0.7 mg clonidine has been administered. A single dose may be all that is necessary. Labetalol can be given in a dose of 200 to 400 mg, followed by additional doses every 2 to 3 hours.

Oral or sublingual immediate-release nifedipine has been used for acute BP lowering in the past but is potentially dangerous. This approach produces a rapid reduction in BP. Immediate-release nifedipine should never be used for hypertensive urgencies due risk of causing of severe adverse events such as MIs and strokes.[122]

Hypertensive Emergency

Hypertensive emergencies are those rare situations that require immediate BP reduction to limit new or progressing target-organ damage (see "Classification" under the Arterial Blood Pressure section). Hypertensive emergencies require parenteral therapy, at least initially, with one of the agents listed in Table 19–11. The goal in

TABLE 19-11 Parenteral Antihypertensive Agents for Hypertensive Emergency

Drug	Dose	Onset (minutes)	Duration (minutes)	Adverse Effects	Special Indications
Clevidipine	1–2 mg/h (32 mg/h max)	2–4	5–15	Headache, nausea, tachycardia, hypertriglyceridemia	Most hypertensive emergencies except acute heart failure; caution with coronary ischemia; contraindicated in soy or egg allergy or if defective lipid metabolism
Enalaprilat	1.25–5 mg intravenous every 6 h	15–30	360–720	Precipitous fall in pressure in high-renin states; variable response	Acute left ventricular failure; avoid in acute myocardial infarction
Esmolol hydrochloride	250–500 mcg/kg/min intravenous bolus, then 50–100 mcg/kg/min intravenous infusion; may repeat bolus after 5 minutes or increase infusion to 300 mcg/min	1–2	10–20	Hypotension, nausea, asthma, first-degree heart block, heart failure	Aortic dissection; perioperative
Fenoldopam mesylate	0.1–0.3 mcg/kg/min intravenous infusion	< 5	30	Tachycardia, headache, nausea, flushing	Most hypertensive emergencies; caution with glaucoma
Hydralazine hydrochloride	12–20 mg intravenous 10–50 mg intramuscular	10–20 20–30	60–240 240–360	Tachycardia, flushing, headache vomiting, aggravation of angina	Eclampsia
Labetalol hydrochloride	20–80 mg intravenous bolus every 10 min; 0.5–2.0 mg/min intravenous infusion	5–10	180–360	Vomiting, scalp tingling, bronchoconstriction, dizziness, nausea, heart block, orthostatic hypotension	Most hypertensive emergencies except acute heart failure
Nicardipine hydrochloride	5–15 mg/h intravenous	5–10	15–30, may exceed 240	Tachycardia, headache, flushing, local phlebitis	Most hypertensive emergencies except acute heart failure; caution with coronary ischemia
Nitroglycerin	5–100 mcg/min intravenous infusion	2–5	5–10	Headache, vomiting, methemoglobinemia, tolerance with prolonged use	Coronary ischemia
Sodium nitroprusside	0.25–10 mcg/kg/min intravenous infusion (requires special delivery system)	Immediate	1–2	Nausea, vomiting, muscle twitching, sweating, thiocynate and cyanide intoxication	Most hypertensive emergencies; caution with high intracranial pressure, azotemia, or in chronic kidney disease

hypertensive emergencies is not to lower BP to less than 140/90 mm Hg; rather, the initial target is a reduction in MAP of up to 25% within minutes to hours. If the patient is then stable, BP can be reduced toward 160/100 mm Hg to 160/110 mm Hg within the next 2 to 6 hours. Precipitous drops in BP may lead to end-organ ischemia or infarction. If patients tolerate this reduction well, additional gradual reductions toward goal BP values can be attempted after 24 to 48 hours. The exception to this guideline is for patients with an acute ischemic stroke where maintaining an elevated BP is needed for a much longer period of time.

The clinical situation should dictate which intravenous medication is used to treat hypertensive emergencies. Regardless, therapy should be provided in a hospital or emergency room setting with intraarticular BP monitoring. Table 19–11 lists special indications for agents that can be used.

Nitroprusside is widely considered the agent of choice for most cases, but it can be problematic for patients with chronic kidney disease. It is a direct-acting vasodilator that decreases peripheral vascular resistance but does not increase CO unless left ventricular failure is present. Nitroprusside can be given to treat most hypertensive emergencies, but in aortic dissection, propranolol should be given first to prevent reflex sympathetic activation. Nitroprusside is metabolized to cyanide and then to thiocyanate, which is eliminated by the kidneys. Therefore, serum thiocyanate levels should be monitored when infusions are continued longer than 72 hours. Nitroprusside should be discontinued if the concentration exceeds 12 mg/dL. The risk of thiocyanate accumulation and toxicity is increased for patients with impaired kidney function.

Intravenous nitroglycerin dilates both arterioles and venous capacitance vessels, thereby reducing both cardiac afterload and cardiac preload, which can decrease myocardial oxygen demand. It also dilates collateral coronary blood vessels and improves perfusion to ischemic myocardium. These properties make intravenous nitroglycerin ideal for the management of hypertensive emergency in the presence of myocardial ischemia. Intravenous nitroglycerin is associated with tolerance when used over 24 to 48 hours and can cause severe headache.

Fenoldopam, nicardipine, and clevidipine are newer and more expensive agents. Fenoldopam is a dopamine-1 agonist. It can improve renal blood flow and may be especially useful for patients with kidney insufficiency. Nicardipine and clevidipine are dihydropyridine CCBs that provides arterial vasodilatation and can treat cardiac ischemia similar to nitroglycerin, but they may provide more predictable reductions in BP.

The hypotensive response of hydralazine is less predictable than with other parenteral agents. Therefore, its major role is in the treatment of eclampsia or hypertensive encephalopathy associated with renal insufficiency.

CONCLUSIONS

Hypertension is a very common medical condition in the United States. Treatment of patients with hypertension should include both lifestyle modifications and pharmacotherapy. Outcome-based studies have definitively demonstrated that treating hypertension reduces the risk of CV events and subsequently reduces morbidity and mortality. Moreover, evidence evaluating individual drug classes has resulted in an evidence-based approach to selecting pharmacotherapy in an individual patient, which is outlined in the JNC7 and 2007 AHA guidelines. Thiazide-type diuretics, ACE inhibitors, ARBs, and CCBs are all first-line agents. Data suggests that using a β-blocker as the primary agent to treat patients with hypertension, without the presence of a compelling indication, may not be as beneficial in reducing risk of CV events compared to thiazide-type diuretic, ACE inhibitor, ARB, or CCB-based therapy. Therefore, they are not first-line therapy options unless an appropriate compelling indication is present.

An often overlooked concept in managing hypertension is to treat patients to a goal BP value. In addition to selecting the most appropriate agent, attaining a goal BP is also of paramount importance to ensure maximum reduction in risk for CV events is provided. A BP goal of at least less than 140/90 mm Hg is recommended for most patients with hypertension and some patients are candidates for lower goal values. Most patients with hypertension require more than one pharmacologic agent to attain goal BP values; therefore, combination therapy is often needed.

Optimizing hypertension management can be achieved many ways. Team-based approaches to implement care and attain goal BP values are effective. Judicious use of cost effective treatments and fixed-dose combination products should always be considered to improve sustainability of treatment. Lastly, interventions to reinforce adherence and lifestyle modifications also are highly recommended in the comprehensive management of hypertension.

CHAPTER 20

Systolic Heart Failure

ROBERT B. PARKER AND LARISA H. CAVALLARI

KEY CONCEPTS

1. Heart failure is a clinical syndrome caused by the inability of the heart to pump sufficient blood to meet the metabolic needs of the body. It can result from any disorder that reduces ventricular filling (diastolic dysfunction) and/or myocardial contractility (systolic dysfunction). The leading causes of heart failure are coronary artery disease and hypertension. The primary manifestations of the syndrome are dyspnea, fatigue, and fluid retention.

2. Heart failure is a progressive disorder that begins with myocardial injury. In response to the injury, several compensatory responses are activated in an attempt to maintain adequate cardiac output, including activation of the sympathetic nervous system (SNS) and the renin–angiotensin–aldosterone system (RAAS), resulting in vasoconstriction and sodium and water retention, as well as ventricular hypertrophy/remodeling. These compensatory mechanisms are responsible for the symptoms of heart failure and contribute to disease progression.

3. Our current understanding of heart failure pathophysiology is best described by the neurohormonal model. Activation of endogenous neurohormones, including norepinephrine, angiotensin II, aldosterone, vasopressin, and numerous proinflammatory cytokines, plays an important role in ventricular remodeling and the subsequent progression of heart failure. Pharmacotherapy targeted at antagonizing this neurohormonal activation has slowed the progression of heart failure and improved survival.

4. Most patients with symptomatic heart failure should be routinely treated with an angiotensin-converting enzyme (ACE) inhibitor, a β-blocker, and a diuretic. The benefits of these medications on slowing heart failure progression, reducing morbidity and mortality, and improving symptoms are clearly established. Patients should be treated with a diuretic if there is evidence of fluid retention. Treatment with digoxin may also be considered to improve symptoms and reduce hospitalizations.

5. In patients with heart failure, ACE inhibitors improve survival, slow disease progression, reduce hospitalizations, and improve quality of life. The doses for these agents should be targeted at those shown in clinical trials to improve survival. When ACE inhibitors are contraindicated or not tolerated, an angiotensin II receptor blocker and the combination of hydralazine and isosorbide dinitrate are reasonable alternatives. Patients with asymptomatic left ventricular dysfunction and/or a previous myocardial infarction (MI; stage B of the American College of Cardiology/American Heart Association [ACC/AHA] classification scheme) should also receive ACE inhibitors, with the goal of preventing symptomatic heart failure and reducing mortality.

6. The β-blockers carvedilol, metoprolol controlled release/extended release (CR/XL), and bisoprolol have been shown to prolong survival, decrease hospitalizations and the need for transplantation, and cause "reverse remodeling" of the left ventricle. These agents are recommended for all patients with a reduced left ventricular ejection fraction. Therapy must be instituted at low doses, with slow upward titration to the target dose.

7. Although chronic diuretic therapy frequently is used in patients with heart failure, it is not mandatory. Diuretic therapy, along with sodium restriction, is required only in those patients with peripheral edema and/or pulmonary congestion. Many patients will need continued diuretic therapy to maintain euvolemia after fluid overload is resolved.

8. Digoxin does not improve survival in patients with heart failure but does provide symptomatic benefits. Digoxin doses should be adjusted to achieve plasma concentrations of 0.5 to 1.0 ng/mL; higher plasma concentrations are not associated with additional benefits but may be associated with increased risk of toxicity.

9. Aldosterone antagonism with low-dose spironolactone has been shown to reduce mortality in patients with New York Heart Association (NYHA) class III and IV heart failure and thus should be strongly considered in these patients provided that potassium levels and renal function can be carefully monitored. Aldosterone antagonists should also be considered soon after MI in patients with left ventricular dysfunction and either heart failure or diabetes.

10. The combination of hydralazine and nitrates has been shown to improve the composite endpoint of mortality, hospitalizations for heart failure, and quality of life in African Americans receiving standard therapy. Current guidelines recommend the addition of hydralazine and nitrates to self-described African Americans with moderate to severe symptoms despite therapy with ACE inhibitors, diuretics, and β-blockers. This combination is also reasonable to consider in all patients who continue to have symptoms despite optimized therapy with an ACE inhibitor (or angiotensin receptor blocker [ARB]) and β-blocker. Hydralazine and a nitrate might

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

be reasonable in patients unable to tolerate either an ACE inhibitor or an ARB because of renal insufficiency, hyperkalemia, or hypotension.

⓫ Pharmacists should play an important role as part of a multidisciplinary team to optimize therapy in heart failure. They should be responsible for such activities as optimizing regimens for heart failure drug therapy (namely, ensuring that appropriate drugs at appropriate doses are used), educating patients about the importance of adherence to their heart failure regimen (including pharmacologic and dietary interventions), screening for drugs that may exacerbate or worsen heart failure, and monitoring for adverse drug effects and drug interactions.

① ② Heart failure is a progressive clinical syndrome that can result from any abnormality in cardiac structure or function that impairs the ability of the ventricle to fill with or eject blood, thus rendering the heart unable to pump blood at a rate sufficient to meet the metabolic demands of the body.[1] It is the final common pathway for numerous cardiac disorders, including those affecting the pericardium, heart valves, and myocardium. Diseases that adversely affect ventricular diastole (filling), ventricular systole (contraction), or both can lead to heart failure. For many years it was believed that reduced myocardial contractility, or systolic dysfunction (i.e., reduced left ventricular ejection fraction [LVEF]), was the sole disturbance in cardiac function responsible for heart failure. However, it is now recognized that large numbers of patients with the heart failure syndrome have relatively normal systolic function (i.e., normal LVEF). This is now referred to as heart failure with preserved LVEF and is believed to be primarily due to diastolic dysfunction of the heart.[1] Recent estimates suggest approximately 50% of patients with heart failure have preserved LVEF with disturbances in relaxation (lusitropic) properties of the heart, or diastolic dysfunction.[2] However, regardless of the etiology of heart failure, the underlying pathophysiologic process and principal clinical manifestations (fatigue, dyspnea, and volume overload) are similar and appear to be independent of the initial cause. Historically, this disorder was commonly referred to as *congestive heart failure*; the preferred nomenclature is now *heart failure,* because a patient may have the clinical syndrome of heart failure without having symptoms of congestion. This chapter will focus on treatment of patients with systolic heart failure due to systolic dysfunction (with or without concurrent diastolic dysfunction). Chapters 21 and 22 discuss the treatment of heart failure with preserved LVEF (diastolic dysfunction) and acute decompensated heart failure, respectively.

EPIDEMIOLOGY

Heart failure is an epidemic public health problem in the United States. Nearly 6 million Americans have heart failure, with an additional 670,000 cases diagnosed each year.[3] Unlike most other cardiovascular diseases, the incidence, prevalence, and hospitalization rates associated with heart failure are increasing and are expected to continue to increase over the next few decades as the population ages. A large majority of patients with heart failure are elderly, with multiple comorbid conditions that influence morbidity and mortality.[3,4] The incidence of heart failure doubles with each decade of life and affects nearly 10% of individuals over age 75. Improved survival after myocardial infarction (MI) is thought to be a likely contributor to the increased incidence and prevalence of heart failure.[4] Heart failure is the most common hospital discharge diagnosis in individuals over age 65. Annual hospital discharges for heart failure now total over 1 million, a 174% increase over the last 2 decades.[3] Heart failure also has a tremendous economic impact, with this expected to increase markedly as the baby boom generation ages. Current estimates suggest annual expenditures for heart failure of approximately $37 billion, with the majority of these costs spent on hospitalized patients.[3] In the United States, over $3 billion is spent annually on drug therapy for heart failure.[3] Thus, heart failure is a major medical problem, with a substantial economic impact that is expected to become even more significant as the population ages.

Despite prodigious advances in our understanding of the etiology, pathophysiology, and pharmacotherapy of heart failure, the prognosis for patients with this disorder remains grim. Although the mortality rates have declined over the past 50 years, the overall 5-year survival remains approximately 50% for all patients with a diagnosis of heart failure, with mortality increasing with symptom severity.[5] For patients under age 65, 80% of men and 70% of women will die within 8 years. Death is classified as sudden in about 40% of patients, implicating serious ventricular arrhythmias as the underlying cause in many patients.[1,5] Factors affecting the prognosis of patients with heart failure include, but are not limited to, age, gender, LVEF, renal function, diabetes, anemia, extent of underlying coronary artery disease, blood pressure, heart failure etiology, and drug or device therapy. Recent models incorporating these and other factors enable clinicians to develop reliable estimates of an individual patient's prognosis.[6,7]

ETIOLOGY

① ② Heart failure can result from any disorder that affects the ability of the heart to contract (systolic function) and/or relax (diastolic dysfunction); common causes of heart failure are shown in Table 20–1.[8] Heart failure with impaired systolic function (i.e., reduced LVEF) is the classic, more familiar form of the disorder, but current estimates suggest up to 50% of patients with heart failure have preserved left ventricular systolic function with presumed diastolic dysfunction.[2] In contrast to systolic heart failure that is usually caused by previous MI, patients with preserved LVEF typically are elderly, female, obese, and have hypertension, atrial fibrillation, or diabetes.[2] Recent data indicate that survival is similar in patients with impaired or preserved LVEF.[2] Common cardiovascular diseases such as MI and hypertension can cause both

TABLE 20-1 Causes of Heart Failure

Systolic dysfunction (decreased contractility)
- Reduction in muscle mass (e.g., myocardial infarction)
- Dilated cardiomyopathies
- Ventricular hypertrophy
  - Pressure overload (e.g., systemic or pulmonary hypertension, and aortic or pulmonic valve stenosis)
  - Volume overload (e.g., valvular regurgitation, shunts, and high-output states)

Diastolic dysfunction (restriction in ventricular filling)
- Increased ventricular stiffness
  - Ventricular hypertrophy (e.g., hypertrophic cardiomyopathy; other examples above)
  - Infiltrative myocardial diseases (e.g., amyloidosis, sarcoidosis, and endomyocardial fibrosis)
  - Myocardial ischemia and infarction
- Mitral or tricuspid valve stenosis
- Pericardial disease (e.g., pericarditis and pericardial tamponade)

systolic and diastolic dysfunction; thus, many patients have heart failure as a result of reduced myocardial contractility and abnormal ventricular filling. Heart failure with preserved LVEF is discussed in Chapter 21.

1 Coronary artery disease is the most common cause of systolic heart failure, accounting for nearly 70% of cases.[4] MI leads to reduction in muscle mass due to the death of affected myocardial cells. The degree to which contractility is impaired will depend on the size of the infarction. In an attempt to maintain cardiac output, the surviving myocardium undergoes a compensatory remodeling, thus beginning the maladaptive process that initiates heart failure syndrome and leads to further injury to the heart. This is discussed in greater detail in the Pathophysiology section. Myocardial ischemia and infarction also affect the diastolic properties of the heart by increasing ventricular stiffness and slowing ventricular relaxation. Thus, MI frequently results in systolic and diastolic dysfunction.

Impaired systolic function is a cardinal feature of dilated cardiomyopathies. Although the cause of reduced contractility frequently is unknown, abnormalities such as interstitial fibrosis, cellular infiltrates, cellular hypertrophy, and myocardial cell degeneration are seen commonly on histologic examination. Genetic causes of dilated cardiomyopathies may also occur.[9]

Pressure or volume overload causes ventricular hypertrophy, which attempts to return contractility to a near-normal state. If the pressure or volume overload persists, the remodeling process results in alterations in the geometry of the hypertrophied myocardial cells and is accompanied by increased collagen deposition in the extracellular matrix. Thus, both systolic and diastolic function may be impaired.[8] Examples of pressure overload include systemic or pulmonary hypertension and aortic or pulmonic valve stenosis.

Hypertension remains an important cause and/or contributor to heart failure in many patients, particularly women, the elderly, and African Americans.[1] The role of hypertension should not be underestimated because hypertension is an important risk factor for ischemic heart disease and thus is also present in a high percentage of patients with this disorder. A recent analysis emphasized that heart failure is a largely preventable disorder. Modifiable risk factors such as uncontrolled hypertension, coronary heart disease, smoking, and chronic kidney disease are strongly associated with increased risk of heart failure.[10] Thus, appropriate management of cardiovascular risk is key to minimizing the risk of heart failure development.

PATHOPHYSIOLOGY

NORMAL CARDIAC FUNCTION

To understand the pathophysiologic processes in heart failure, a basic understanding of normal cardiac function is necessary. *Cardiac output* (CO) is defined as the volume of blood ejected per unit time (L/min) and is the product of heart rate (HR) and stroke volume (SV):

$$CO = HR \times SV$$

The relationship between CO and mean arterial pressure (MAP) is

$$MAP = CO \times \text{systemic vascular resistance (SVR)}$$

Heart rate is controlled by the autonomic nervous system. Stroke volume, or the volume of blood ejected during systole, depends on preload, afterload, and contractility.[8] As defined by the Frank-Starling mechanism, the ability of the heart to alter the force of contraction depends on changes in preload. As myocardial sarcomere length is stretched, the number of cross-bridges between thick and thin myofilaments increases, resulting in an increase in the force of contraction. The length of the sarcomere is determined primarily by the volume of blood in the ventricle; therefore, left ventricular end-diastolic volume (LVEDV) is the primary determinant of preload. In normal hearts, the preload response is the primary compensatory mechanism such that a small increase in end-diastolic volume results in a large increase in cardiac output. Because of the relationship between pressure and volume in the heart, left ventricular end-diastolic pressure (LVEDP) is often used in the clinical setting to estimate preload. The hemodynamic measurement used to estimate LVEDP is the pulmonary artery occlusion pressure (PAOP). Afterload is a more complex physiologic concept that can be viewed pragmatically as the sum of forces preventing active forward ejection of blood by the ventricle. Major components of global ventricular afterload are ejection impedance, wall tension, and regional wall geometry. In patients with left ventricular systolic dysfunction, an inverse relationship exists between afterload (or SVR) and stroke volume such that increasing afterload causes a decrease in stroke volume (Fig. 20–1). Contractility is the intrinsic property of cardiac muscle describing fiber shortening and tension development.

COMPENSATORY MECHANISMS IN HEART FAILURE

2 Heart failure is a progressive disorder initiated by an event that impairs the ability of the heart to contract and/or relax, resulting in a decrease in cardiac output. The index event may have an acute onset, as with MI, or the onset may be slow, as with long-standing hypertension. Regardless of the index event, the decrease in the heart's pumping capacity results in the heart having to rely on compensatory responses to maintain an adequate cardiac output.[11] These compensatory responses include (a) tachycardia and increased contractility through sympathetic nervous system (SNS) activation; (b) the Frank-Starling mechanism, whereby an increase in preload results in an increase in stroke volume; (c) vasoconstriction; and (d) ventricular hypertrophy and remodeling. Compensatory responses are intended to provide short-term support to maintain circulatory homeostasis after acute reductions in blood pressure or renal perfusion. However, the persistent decline in cardiac output in heart failure leads to long-term activation of these compensatory

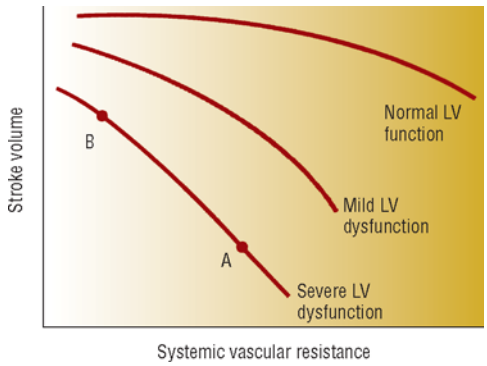

FIGURE 20-1. Relationship between stroke volume and systemic vascular resistance. In an individual with normal left ventricular (LV) function, increasing systemic vascular resistance has little effect on stroke volume. As the extent of LV dysfunction increases, the negative, inverse relationship between stroke volume and systemic vascular resistance becomes more important (*B* to *A*).

TABLE 20-2 Beneficial and Detrimental Effects of the Compensatory Responses in Heart Failure

Compensatory Response	Beneficial Effects of Compensation	Detrimental Effects of Compensation
Increased preload (through Na^+ and water retention)	Optimize stroke volume via Frank-Starling mechanism	Pulmonary and systemic congestion and edema formation Increased MVO_2
Vasoconstriction	Maintain BP in face of reduced CO Shunt blood from nonessential organs to brain and heart	Increased MVO_2 Increased afterload decreases stroke volume and further activates the compensatory responses
Tachycardia and increased contractility (due to SNS activation)	Helps maintain CO	Increased MVO_2 Shortened diastolic filling time β_1-receptor downregulation, decreased receptor sensitivity Precipitation of ventricular arrhythmias Increased risk of myocardial cell
Ventricular hypertrophy and remodeling	Helps maintain CO Reduces myocardial wall stress Decreases MVO_2	Diastolic dysfunction Systolic dysfunction Increased risk of myocardial cell death Increased risk of myocardial ischemia Increased arrhythmia risk Fibrosis

Abbreviations: BP, blood pressure; CO, cardiac output; MVO_2, myocardial oxygen demand; SNS, sympathetic nervous system.

responses, resulting in the complex functional, structural, biochemical, and molecular changes important for the development and progression of heart failure. The beneficial and detrimental effects of these compensatory responses are described later in this chapter and are summarized in Table 20–2.

Tachycardia and Increased Contractility

The change in heart rate and contractility that rapidly occurs in response to a drop in cardiac output is primarily due to the release of norepinephrine from adrenergic nerve terminals, although parasympathetic nervous system activity is also diminished. Cardiac output increases with heart rate until diastolic filling becomes compromised, which in the normal heart is at 170 to 200 beats per minute. Loss of atrial contribution to ventricular filling also can occur (atrial fibrillation, ventricular tachycardia), reducing ventricular performance even more. Because ionized calcium is sequestered into the sarcoplasmic reticulum and pumped out of the cell during diastole, shortened diastolic time also results in a higher average intracellular calcium concentration during diastole, increasing actin—myosin interaction, augmenting the active resistance to fibril stretch, and reducing lusitropy. Conversely, the higher average calcium concentration translates into greater filament interaction during systole, generating more tension.[8] Increasing heart rate greatly increases myocardial oxygen demand. If ischemia is induced or worsened, both diastolic and systolic function may become impaired, and stroke volume can drop precipitously. In addition, polymorphisms in genes coding for adrenergic receptors (e.g., β_1 and α_{2c} receptors) and their signaling pathways appear to alter the response to endogenous norepinephrine and affect the risk for the development of heart failure.[12,13]

Fluid Retention and Increased Preload

Augmentation of preload is another compensatory response that is rapidly activated in response to decreased cardiac output. Renal perfusion in heart failure is reduced due to both depressed cardiac output and redistribution of blood away from nonvital organs. The kidney interprets the reduced perfusion as an ineffective blood volume, resulting in activation of the renin—angiotensin—aldosterone system (RAAS) in an attempt to maintain blood pressure and increase renal sodium and water retention. Reduced renal perfusion and increased sympathetic tone also stimulate renin release from juxtaglomerular cells in the kidney. As shown in Figure 20–2, renin is responsible for conversion of angiotensinogen to angiotensin I. Angiotensin I is converted to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II may also be generated via non-ACE-dependent pathways. Angiotensin II stimulates aldosterone release from the adrenal gland, thereby providing an additional mechanism for renal sodium and water retention. As intravascular volume increases secondary to sodium and water retention, left ventricular volume and pressure (preload) increase, sarcomeres are stretched, and the force of contraction is enhanced.[8] Although the preload response is the primary compensatory mechanism in normal hearts, the chronically failing heart usually has exhausted its preload reserve.[8] As shown in Figure 20–3, increases in preload will increase stroke volume only to a certain point. Once the flat portion of the curve is reached, further increases in preload will only lead to pulmonary or systemic congestion, a detrimental result.[8] Figure 20–3 also shows that the curve is flatter in patients with left ventricular dysfunction. Consequently, a given increase in preload in a patient with heart failure will produce a smaller increment in stroke volume than in an individual with normal ventricular function.

Vasoconstriction and Increased Afterload

Vasoconstriction occurs in patients with heart failure to help redistribute blood flow away from nonessential organs to coronary and cerebral circulations to support blood pressure, which may be reduced secondary to a decrease in cardiac output (MAP = CO × SVR).[8] A number of neurohormones likely contribute to the vasoconstriction, including norepinephrine, angiotensin II, endothelin-1, neuropeptide Y, and arginine vasopressin (AVP).[8,14] Vasoconstriction impedes forward ejection of blood from the ventricle, further depressing cardiac output and heightening the compensatory responses. Because the failing ventricle usually has exhausted its preload reserve (unless the patient is intravascularly depleted), its performance is exquisitely sensitive to changes in afterload (Fig. 20–1). Thus, increases in afterload often potentiate a vicious cycle of continued worsening and downward spiraling of the heart failure state.

Ventricular Hypertrophy and Remodeling

❸ Although the signs and symptoms of heart failure are closely associated with the items described above, the progression of heart failure appears to be independent of the patient's hemodynamic

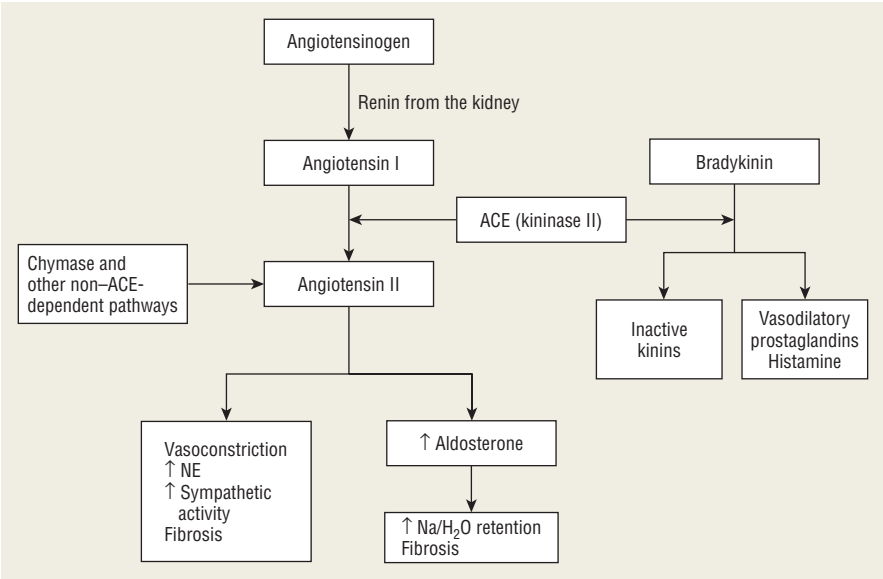

FIGURE 20-2. Physiology of the renin-angiotensin-aldosterone system. Renin produces angiotensin I from angiotensinogen. Angiotensin I is cleaved to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II has a number of physiologic actions that are detrimental in heart failure. Note that angiotensin II can be produced in a number of tissues, including the heart, independent of ACE activity. ACE is also responsible for the breakdown of bradykinin. Inhibition of ACE results in accumulation of bradykinin that, in turn, enhances the production of vasodilatory prostaglandins. (NE, norepinephrine.)

status. It is now recognized that ventricular hypertrophy and remodeling are key components in the pathogenesis of progressive myocardial failure.[8,11] *Ventricular hypertrophy* is a term used to describe an increase in ventricular muscle mass. *Cardiac* or *ventricular remodeling* is a broader term describing changes in both myocardial cells and extracellular matrix that result in changes in the size, shape, structure, and function of the heart. These progressive changes in ventricular structure and function ultimately result in a change in the shape of the left ventricle from an ellipse to a sphere. This change in ventricular size and shape serves to further depress the mechanical performance of the heart, increases regurgitant flow through the mitral valve, and, in turn, fuels the continued progression of remodeling. Ventricular hypertrophy and remodeling can occur in association with any condition that causes myocardial injury, including MI, cardiomyopathy, hypertension, and valvular heart disease. The onset of the remodeling process precedes the development of heart failure symptoms.

Cardiac remodeling is a complex process that affects the heart at the molecular and cellular level. Key elements in the process are shown in Figure 20–4. Collectively, these events result in progressive changes in myocardial structure and function, such as cardiac hypertrophy, myocyte loss, and alterations in the extracellular matrix. The progression of the remodeling process leads to reductions in myocardial systolic and/or diastolic function that, in turn, result in further myocardial injury, perpetuating the remodeling process and the decline in ventricular dysfunction. Angiotensin II, norepinephrine, endothelin, aldosterone, vasopressin, and numerous inflammatory cytokines, as well as substances under investigation that are activated both systemically and locally in the heart and vasculature, play an important role in initiating the signal-transduction cascade responsible for ventricular remodeling. Although these mediators produce deleterious effects on the heart, their increased circulating and tissue concentrations play important roles in other organs, such as the brain, that serve to sustain the heart failure syndrome.[15] This serves as an important reminder that heart failure is a systemic as well as a cardiac disorder.

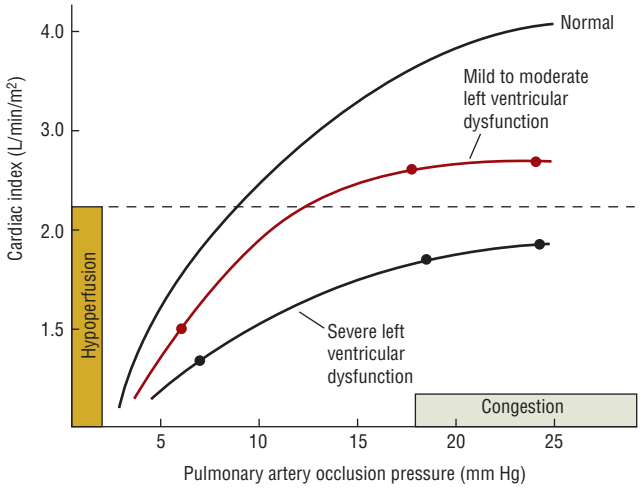

FIGURE 20-3. Relationship between cardiac output (shown as cardiac index, which is cardiac output [CO]/body surface area [BSA]) and preload (shown as pulmonary artery occlusion pressure).

Pressure overload (and probably hormonal activation) associated with hypertension produces a concentric hypertrophy (increase in the ventricular wall thickness without chamber enlargement). Conversely, eccentric left ventricular hypertrophy (myocyte lengthening with increased chamber size with minimal increase in wall thickness) characterizes the hypertrophy seen in patients with systolic dysfunction or previous MI. As the myocytes undergo change, so do various components of the extracellular matrix. For example, there is evidence for collagen degradation, which may lead to slippage of myocytes, fibroblast proliferation, and increased fibrillar collagen synthesis, resulting in fibrosis and stiffening of the entire myocardium. Thus, a number of important ventricular changes that occur with remodeling include changes in the geometry of the heart from an elliptical to spherical shape, increases in ventricular mass (from myocyte hypertrophy), and changes in ventricular composition (especially the extracellar matrix) and volumes, all of which likely contribute to the impairment of cardiac function. If the event that produces cardiac injury is acute (e.g., MI), the ventricular remodeling process begins immediately. However, it is the progressive nature of this process that results in continual worsening of the heart failure state, and thus is now the major focus for identification of therapeutic targets. In fact, it is believed that all the heart failure therapies that have been associated with decreased mortality and/or slowing of the progression of the disease produce this effect largely through their ability to slow or reverse the ventricular remodeling

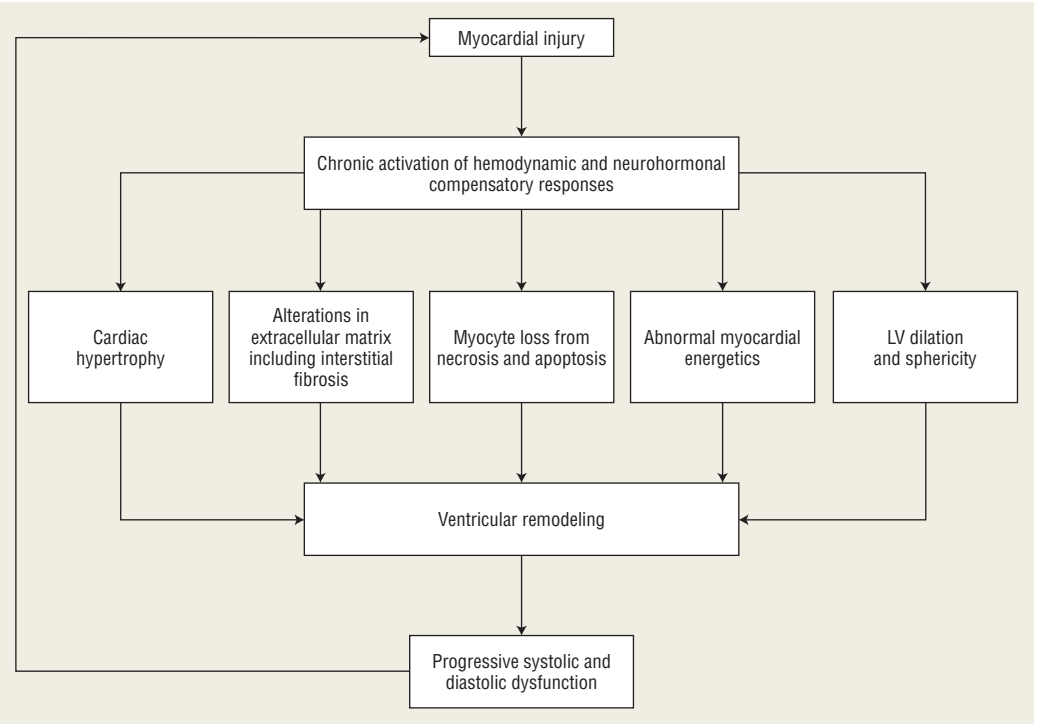

FIGURE 20-4. Key components of the pathophysiology of cardiac remodeling. Myocardial injury (e.g., myocardial infarction) results in the activation of a number of hemodynamic and neurohormonal compensatory responses in an attempt to maintain circulatory homeostasis. Chronic activation of the neurohormonal systems results in a cascade of events that affect the myocardium at the molecular and cellular levels. These events lead to the changes in ventricular size, shape, structure, and function known as ventricular remodeling. The alterations in ventricular function result in further deterioration in cardiac systolic and diastolic function, which further promotes the remodeling process. (LV, left ventricular.)

process, a process often referred to as *reverse remodeling*. Thus, while ventricular hypertrophy and remodeling may have some beneficial effects by helping maintain cardiac output, they also are believed to play an essential role in the progressive nature of heart failure.

THE NEUROHORMONAL MODEL OF HEART FAILURE AND THE THERAPEUTIC INSIGHTS IT PROVIDES

2 3 Over the years, several different paradigms have guided our understanding of the pathophysiology and treatment of heart failure.[8,11,16] The early paradigm, often called the *cardiorenal model,* viewed the problem as excess sodium and water retention, and diuretic therapy was the main therapeutic approach. The next paradigm, the *cardiocirculatory model,* focused on impaired cardiac output (viewed as being due to both the reduced pumping capacity of the heart and systemic vasoconstriction). This paradigm focused on positive inotropes and, later, vasodilators as the primary therapies to overcome reductions in cardiac output. Although the therapeutic approaches associated with these paradigms provided some symptomatic benefits to patients with heart failure, they did little to slow progression of the disease. In fact, the detrimental effects of positive inotropic drugs on survival highlighted the inadequacy of the cardiocirculatory model to explain the progressive nature of heart failure. Initial studies with ACE inhibitors were conducted with the thought that they might be effective due to their balanced (arterial and venous) vasodilation. Subsequent realization that ACE inhibitors were providing benefit beyond their vasodilating effects, followed by the positive results with β-adrenergic receptor blockers and aldosterone antagonists, has led to the current paradigm used to describe heart failure: the *neurohormonal model.* This model recognizes that there is an initiating event (e.g., MI, long-standing hypertension) that leads to decreased cardiac output and begins the "heart failure state." Subsequently, the problem moves beyond the heart, and it becomes a systemic disease whose progression is mediated largely by neurohormones and autocrine/paracrine factors that drive myocyte injury, oxidative stress, inflammation, and extracellular-matrix remodeling. Although the former paradigms still guide us to some extent in the symptomatic management of the disease (e.g., diuretics and digoxin), it is the latter paradigm that helps us understand disease progression, in particular, the ways to slow disease progression. In the sections that follow, key neurohormones and autocrine/paracrine factors, sometimes now collectively termed *biomarkers,* are described with respect to their role in heart failure and its progression. The benefits of current and investigational drug therapies can be better understood through a solid understanding of the neurohormones they regulate/affect. Although the neurohormonal model provides a logical framework for our current understanding of heart failure progression and the role of various medications in attenuating this progression, it must be emphasized that this model does not completely explain heart failure progression. For example, drug therapies that target the neurohormonal perturbations in heart failure usually only slow the progressive nature of the disorder rather than completely stop it. Ongoing research will likely identify additional targets for drug therapy.

Angiotensin II

Of the neurohormones and autocrine/paracrine factors that play an important role in the pathophysiology of heart failure, angiotensin II is probably the best understood.[8,11] Although

circulating angiotensin II produced from ACE activity is the most familiar route for generation of angiotensin II, recent evidence indicates that this hormone is synthesized directly in the myocardium through non-ACE-dependent pathways. This tissue production of angiotensin II also plays an important role in heart failure pathophysiology. Angiotensin II has multiple actions that contribute to its detrimental effects in heart failure. It increases systemic vascular resistance directly by binding to the angiotensin I receptor in the vasculature and promoting potent vasoconstriction and indirectly by causing release of AVP and endothelin-1. Angiotensin II also facilitates the release of norepinephrine from adrenergic nerve terminals, heightening SNS activation. It promotes sodium retention through direct effects on the renal tubules and by stimulating aldosterone release. Its vasoconstriction of the efferent glomerular arteriole helps to maintain perfusion pressure in patients with severe heart failure or impaired renal function. Thus, in patients dependent on angiotensin II for maintenance of perfusion pressure, initiation of an ACE inhibitor or a type I angiotensin receptor blocker (ARB) causes efferent arteriole vasodilation, decreased perfusion pressure, and decreased glomerular filtration. This explains the risk of transient impairment in renal function associated with initiation of ACE inhibitor or ARB therapy. Finally, angiotensin II and many of the neurohormones released in response to angiotensin II play a central role in stimulating ventricular hypertrophy, remodeling, myocyte apoptosis (programmed cell death), oxidative stress, inflammation, and alterations in the extracellular matrix. Clinical data suggest that blocking angiotensin II-mediated effects contributes substantially to the prolonged survival of patients treated with ACE inhibitors and ARBs.[17,18] The favorable effects of ACE inhibitors and ARBs on hemodynamics, symptoms, quality of life, and survival in heart failure highlight the importance of angiotensin II in the pathophysiology of heart failure.

Norepinephrine

Many of the detrimental effects of norepinephrine in heart failure are described earlier in this chapter. Norepinephrine plays a central role in the tachycardia, vasoconstriction, and increased contractility observed in heart failure. It also plays a role in the increased plasma renin activity seen in heart failure. Plasma norepinephrine concentrations are elevated in correlation with the degree of heart failure, and patients with the highest concentrations have the poorest prognosis.[8,11,14] In addition to the detrimental effects described, excessive SNS activation causes downregulation of β_1-receptors, with a subsequent loss of sensitivity to receptor stimulation. Evidence suggests that genetic variations in the β_1- and α_{2c}-receptors, which are targets for norepinephrine's actions, may modify the extent of receptor downregulation and increase the risk of heart failure.[12,13] Excess catecholamines increase the risk of arrhythmias and can cause myocardial cell loss by stimulating both necrosis and apoptosis. Finally, norepinephrine contributes to ventricular hypertrophy and remodeling. The detrimental effects of SNS activation are further highlighted by the clinical trials of chronic therapy with β-agonists, phosphodiesterase inhibitors, or other drugs that cause SNS activation, as they have been shown uniformly to increase mortality in heart failure. Conversely, β-blockers, ACE inhibitors, and digoxin all help to decrease SNS activation, through various mechanisms, and are beneficial in heart failure. Thus, it is clear that norepinephrine plays a critical role in the pathophysiology of the heart failure state.

Aldosterone

Aldosterone-mediated sodium retention and its key role in volume overload and edema have long been recognized as important components of the heart failure syndrome.[19,20] Circulating aldosterone is increased in heart failure due to stimulation of its synthesis and release from the adrenal cortex by angiotensin II and to decreased hepatic clearance secondary to reduced hepatic perfusion. Although its enhancement of sodium retention is an important component of heart failure symptoms, recent studies indicate the direct effects of aldosterone on the heart that may be even more important in heart failure pathophysiology. Chief among these is the ability of aldosterone to produce interstitial cardiac fibrosis through increased collagen deposition in the extracellular matrix of the heart. This cardiac fibrosis may decrease systolic function and impair diastolic function by increasing the stiffness of the myocardium. Current research shows that extra-adrenal production of aldosterone in the heart, kidneys, and vascular smooth muscle also contributes to the progressive nature of heart failure through target organ fibrosis and vascular remodeling. Induction of a systemic proinflammatory state, increased oxidative stress, wasting of soft tissues and bone, secondary hyperparathyroidism, and mineral/micronutrient dyshomeostasis are other important pathological actions of aldosterone that directly contribute to ventricular remodeling and heart failure progression.[21] Aldosterone also may increase the risk of ventricular arrhythmias through a number of mechanisms, including creation of reentrant circuits as a result of fibrosis, inhibition of cardiac norepinephrine reuptake, depletion of intracellular potassium and magnesium, and impairment of parasympathetic traffic. Other recently identified detrimental effects of aldosterone are insulin resistance and endothelial and baroreceptor dysfunction. Recent studies demonstrate that the aldosterone antagonists spironolactone[22] and eplerenone[23] produce significant reductions in mortality in patients with heart failure, without appreciable effects on diuresis or hemodynamics, providing substantial evidence that the direct cardiac effects of aldosterone play an important role in heart failure pathophysiology.

Natriuretic Peptides

The natriuretic peptide family has three members: atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP), and C-type natriuretic peptide (CNP).[24–26] ANP is stored mainly in the right atrium, whereas BNP is found primarily in the ventricles. Both are released in response to pressure or volume overload. CNP is found mainly in the brain and has very low plasma concentrations. ANP and BNP plasma concentrations are elevated in patients with heart failure and are thought to balance the effects of the RAAS by causing natriuresis, diuresis, vasodilation, decreased aldosterone release, decreased hypertrophy, and inhibition of the SNS and RAAS.

The development of easily performed commercial assays for BNP and the related biologically inactive peptide, NT-proBNP, resulted in significant attention to the role of these peptides as a biomarker for prognostic, diagnostic, and therapeutic use. In patients with systolic heart failure, the degree of elevation in BNP levels is closely associated with increased mortality, risk of sudden death, symptoms, and hospital readmission. Current data indicate BNP is more sensitive than norepinephrine for predicting morbidity and mortality in patients with heart failure. Accurate diagnosis of acute decompensated heart failure in acute care settings is often difficult, as many of the symptoms (e.g., dyspnea) mimic those of other disorders, such as pulmonary disease and obesity. The most well established clinical application of BNP testing is in the urgent care setting, where the BNP assay is useful when combined with clinical evaluation for discriminating dyspnea secondary to heart failure from other causes. Much interest has focused on the benefits of serial measurement of BNP as a target to guide the titration of drug doses. Recent studies evaluating this approach have not shown consistent improvement in long-term outcomes compared with

standard medical therapy.[27] As a result, current guidelines do not support the routine use of serial measurement of BNP in the management of systolic heart failure.

Arginine Vasopressin

AVP is a pituitary peptide hormone that plays an important role in the regulation of renal water and solute excretion.[16,28] AVP secretion is directly linked to changes in plasma osmolality, thus attempting to maintain body fluid homeostasis. The physiologic effects of AVP are mediated through the V_{1a} and V_2 receptors. V_{1a} receptors are located in vascular smooth muscle and in myocytes, where AVP stimulation results in vasoconstriction and increased cardiac contractility, respectively. V_2 receptors are located in the collecting duct of the kidney, where AVP stimulation causes reabsorption of free water.

Plasma concentrations of AVP are elevated in patients with heart failure, supporting current research that indicates AVP plays a role in the pathophysiology of heart failure. Important effects associated with increased circulating AVP concentrations include (a) increased renal free water reabsorption in the face of plasma hypo-osmolality, resulting in volume overload and hyponatremia; (b) increased arterial vasoconstriction, which contributes to reduced cardiac output; and (c) stimulation of remodeling by cardiac hypertrophy and extracellular matrix collagen deposition.

Given the importance of AVP in heart failure, recent efforts have focused on the development of AVP antagonist drugs for treatment of acute and systolic heart failure. By blocking the AVP receptor, these agents primarily increase free water excretion (i.e., an "aquaretic" effect). Clinical trials with the oral V_2 receptor antagonist tolvaptan indicate it improves acute symptoms and increases serum sodium and urine output without affecting heart rate, blood pressure, renal function, or other electrolytes. However, neither overall mortality nor morbidity from heart failure was improved by tolvaptan treatment.[29] Therefore, the role of chronic therapy with vasopressin antagonists remains uncertain.

Endothelin

The endothelin peptides are potent vasoconstrictors that may be involved in heart failure pathophysiology through a number of mechanisms.[16] Endothelin-1, the best characterized of these peptides, is synthesized by endothelial and vascular smooth muscle cells, with its release enhanced by norepinephrine, angiotensin II, and inflammatory cytokines. Like other peptides and hormones described earlier, endothelin-1 plasma concentrations are elevated in heart failure and have been correlated directly with the severity of hemodynamic abnormality, symptoms, and mortality. Its arterial and venous constrictive effects increase preload and afterload, and its vasoconstriction of both efferent and afferent renal arterioles may decrease renal plasma flow and induce sodium retention. Endothelin-1 has direct cardiotoxic and arrhythmogenic effects and is a potent stimulator of cardiac myocyte hypertrophy. The putative role of endothelin in heart failure led to the development of a number of endothelin-receptor antagonists. Although these agents improved hemodynamics, no benefit on morbidity or mortality has been demonstrated, and further clinical development is unlikely.

Other Circulating Biomarkers

In addition to neurohormones, a number of other biomarkers may play a role in heart failure pathogenesis, risk stratification, and identification of patients at risk for developing heart failure.[16] Inflammation is a key component of the systemic heart failure state, resulting in significant interest in associated biomarkers.[30] Elevated plasma concentrations of the acute phase reactant C-reactive protein are associated with poor outcomes in patients with heart failure. The proinflammatory cytokines tumor necrosis factor-α (TNF-α) and interleukins-1, -6, and -18 have all been shown to be elevated in heart failure, with a direct relationship between the degree of elevation and the severity of heart failure. These cytokines produce multiple deleterious actions, including negative inotropic effects, uncoupling β-adrenergic receptors from adenylyl cyclase (thus reducing β-receptor-mediated responses), increasing myocardial cell apoptosis/necrosis, and stimulating remodeling via several mechanisms.

The role of inflammation and endothelial dysfunction has generated significant interest in the use of a number of antiinflammatory therapies in patients with heart failure. Clinical trials evaluating anti-TNF-α therapies (e.g., etanercept and infliximab) have been disappointing, with no improvement in outcomes demonstrated. In addition to the ability of statins to lower cholesterol and reduce the risk of death and other atherosclerotic vascular diseases, their pleiotropic effects (e.g., antiinflammatory, improved endothelial function, and promotion of angiogenesis) were thought to be beneficial in heart failure. However, two recent major trials with statins failed to show any benefit on important clinical outcomes.[31,32] At this time, statins cannot be recommended for routine use specifically for their benefits in heart failure. Although it is uncertain if reductions are due to antiinflammatory effects, fish oil supplementation reduced total mortality and hospitalizations for cardiovascular disease in patients with heart failure.[33]

Numerous other biomarkers are under investigation for their role in heart failure, including those associated with inflammation, oxidative stress, extracellular matrix remodeling, and myocyte injury and stress. It is hoped that data from investigations will lead to improved understanding of disease pathophysiology, prognosis, and targets for therapy.

FACTORS PRECIPITATING/ EXACERBATING HEART FAILURE

Although significant advancements have been made in treatment, symptom exacerbation, to the point that hospitalization is required, is a common and growing problem in patients with systolic heart failure. Hospitalization for heart failure exacerbation consumes large amounts of healthcare dollars and significantly impairs the patient's quality of life; thus, there is great interest in identifying and then remedying factors that increase the risk of decompensation. Appropriate therapy can often maintain patients in a "compensated" state, indicating that they are relatively symptom-free. However, there are many aggravating or precipitating factors that may cause a previously compensated patient to develop worsened symptoms, necessitating hospitalization. Often, these precipitating factors are reversible or treatable, such that a thorough evaluation for their presence in hospitalized patients is imperative.

Cardiac events are a frequent cause of worsening heart failure.[1,34] Myocardial ischemia and infarction are potentially reversible causes that must be carefully considered, as nearly 70% of patients with heart failure have coronary artery disease. Revascularization should be considered in appropriate patients. Atrial fibrillation occurs in 10% to 50% of patients with heart failure and is associated with increased morbidity and mortality.[35] Atrial fibrillation can exacerbate heart failure through rapid ventricular response and loss of atrial contribution to ventricular filling. Conversely, heart failure can precipitate atrial fibrillation by worsening atrial distention, resulting from ventricular volume overload. Control of ventricular response, maintenance of sinus rhythm in appropriate patients, and prevention of thromboembolism are important elements

in the treatment of heart failure patients with atrial fibrillation. Uncontrolled hypertension is also an important contributing factor and should be treated according to current guidelines.[36]

A number of noncardiac events may also be associated with heart failure decompensation. Pulmonary infections frequently cause worsening of heart failure. Many of these events would be preventable with more widespread use of the pneumococcal and influenza vaccines. Pulmonary embolus, diabetes, worsening renal function, hypothyroidism, and hyperthyroidism should also be considered.

Nonadherence with prescribed heart failure medications or with dietary recommendations (e.g., sodium intake and fluid restriction) are also common causes of heart failure exacerbation.[1,34] Recent estimates indicate that nonadherence accounts for between 3% and 64% of hospital admissions for heart failure and that socioeconomically disadvantaged patients appear to be disproportionately affected.

A number of drugs are associated with the ability to precipitate or exacerbate heart failure by one or more of the following mechanisms: negative inotropic effects, direct cardiotoxicity, or increased sodium and/or water retention (Table 20–3). The resulting symptoms are typically those associated with volume overload, but in more severe cases, hypoperfusion may also be present. Nonsteroidal antiinflammatory drugs (NSAIDs) are increasingly recognized for their ability to exacerbate heart failure through a number of mechanisms, including volume retention, decreased renal function, and increased blood pressure. A recent analysis demonstrated that NSAIDs are associated with increased mortality and hospitalization risk in patients with heart failure.[37]

12 What should be evident is that many of the precipitating factors are preventable, particularly through appropriate pharmacist intervention. Specifically, patient education and counseling by a pharmacist should help to decrease a common reason for heart failure exacerbation: noncompliance with dietary sodium and water restrictions, drug therapy, or both. Pharmacists also should be able to identify and address inadequate heart failure therapy, poorly controlled hypertension, and administration of drugs that may worsen heart failure (Table 20–3). A careful medication history is an important aspect of evaluating the cause(s) of heart failure exacerbation. Discontinuation of medications that may exacerbate heart failure may help prevent hospitalizations. Use of medications such as antiarrhythmic agents and non—dihydropyridine calcium channel blockers are important precipitants of exacerbations. The widespread use of NSAIDs, particularly those obtained over-the-counter that are perceived by many patients as having a low risk of adverse effects, is also problematic, and their use should be discouraged in patients with heart failure. The thiazolidinedione hypoglycemic drugs rosiglitazone and pioglitazone are associated with the development of fluid retention and weight gain that may exacerbate heart failure. Current guidelines indicate these agents should not be used in patients with New York Heart Association (NYHA) class III or IV heart failure.[1,38] Thus, many of the factors precipitating heart failure exacerbations (nonadherence, inadequate/inappropriate drug therapy, uncontrolled hypertension, etc.) are amenable to pharmacist intervention. The value of the pharmacist's role in careful and repeated education of patients and monitoring of the drug regimen should not be underestimated.[39,40] Attention to these factors may make an important contribution to reducing the risk of hospitalization and improving the patient's quality of life.

TABLE 20-3 Drugs that May Precipitate or Exacerbate Heart Failure

Negative inotropic effect
- Antiarrhythmics (e.g., disopyramide, flecainide, and propafenone)
- Beta-blockers (e.g., propranolol, metoprolol, and atenolol)
- Calcium channel blockers (e.g., verapamil and diltiazem)
- Itraconazole
- Terbinafine

Cardiotoxic
- Doxorubicin
- Daunomycin
- Cyclophosphamide
- Trastuzumab
- Ethanol
- Amphetamines (e.g., cocaine and methamphetamine)

Sodium and water retention
- NSAIDs
- COX-2 inhibitors
- Rosiglitazone and pioglitazone
- Glucocorticoids
- Androgens and estrogens
- Salicylates (high-dose)
- Sodium-containing drugs (e.g., carbenicillin disodium and ticarcillin disodium)
- Imatinib

Abbreviations: COX-2, cyclooxygenase-2; NSAIDs, nonsteroidal antiinflammatory drugs.

CLINICAL PRESENTATION

SIGNS AND SYMPTOMS

2 The primary manifestations of heart failure are dyspnea and fatigue, which lead to exercise intolerance, and fluid overload, which can result in pulmonary congestion and peripheral edema.[41] The presence of these signs and symptoms may vary considerably from patient to patient, such that some patients have dyspnea but no signs of fluid retention, whereas others may have marked volume overload with few complaints of dyspnea or fatigue. However, many patients may have both dyspnea and volume overload. Clinicians should remember that symptom severity often does not correlate with the degree of left ventricular dysfunction. Patients with a low LVEF (less than 20–25%) may be asymptomatic, whereas those with preserved LVEF may have significant symptoms. It is also important to note that symptoms can vary considerably over time in a given patient even in the absence of changes in ventricular function or medications.

Historically, signs and symptoms are classified as being due to left ventricular failure (pulmonary congestion) or right ventricular failure (systemic congestion). Because of the complex nature of this syndrome, it has become exceedingly more difficult to attribute a specific sign or symptom as caused by either right or left ventricular failure. Therefore, the numerous signs and symptoms associated with this disorder are collectively attributed to heart failure, rather than due to dysfunction of a specific ventricle.

Pulmonary congestion arises as the left ventricle fails and is unable to accept and eject the increased blood volume that is delivered to it. Consequently, pulmonary venous and capillary pressures rise, leading to interstitial and bronchial edema, increased airway resistance, and dyspnea. The associated signs and symptoms may include (a) dyspnea (with or without exertion), (b) orthopnea, (c) paroxysmal nocturnal dyspnea (PND), and (d) pulmonary edema. Exertional dyspnea occurs when there is a reduction in the level of exertion that causes breathlessness. This is typically described as more breathlessness than was associated previously with a specific activity (e.g., vacuuming, stair climbing). As heart failure progresses, many patients eventually have dyspnea at rest.

Orthopnea is dyspnea that occurs with assumption of the supine position. It occurs within minutes of recumbency and is due to reduced pooling of blood in the lower extremities and abdomen. Orthopnea is relieved almost immediately by sitting upright and typically is prevented by elevating the head with pillows. An increase in the number of pillows required to prevent orthopnea (e.g., a change from "two-pillow" to "three-pillow" orthopnea) suggests worsening heart failure.

Attacks of paroxysmal nocturnal dyspnea or PND typically occur after 2 to 4 hours of sleep; the patient awakens from sleep with a sense of suffocation. The attacks are due to severe pulmonary and bronchial congestion, leading to shortness of breath, cough, and wheezing. The reasons these attacks occur at night are unclear but may include (a) reduced pooling of blood in the lower extremities and abdomen (as with orthopnea), (b) slow resorption of interstitial fluid from sites of dependent edema, (c) normal reduction in sympathetic activity that occurs with sleep (e.g., less support for the failing ventricle), and (d) normal depression in respiratory drive that occurs with sleep.

Rales (crackling sounds heard on auscultation) are present in the lung bases due to transudation of fluid into alveoli. The rales typically are bibasilar, but if heard unilaterally, they are usually right-sided. Rales are not present in most patients with systolic heart failure even though there is volume overload. This is thought to be due to a compensatory increase in lymphatic drainage. Detection of rales is usually indicative of a rapid onset of worsening heart failure rather than the amount of excess fluid volume. A third heart sound, or S_3 gallop, is heard frequently in patients with left ventricular failure and may be due to elevated atrial pressure and altered distensibility of the ventricle.

Pulmonary edema is the most severe form of pulmonary congestion and is caused by accumulation of fluid in the interstitial spaces and alveoli. In patients with heart failure, it is the result of increased pulmonary venous pressure. The patient experiences extreme breathlessness and anxiety and may cough pink, frothy sputum. Pulmonary edema can be terrifying for the patient, causing a feeling of suffocation or drowning. Patients with pulmonary edema may also report any of the above-mentioned signs or symptoms of pulmonary congestion.

Systemic congestion is associated with a number of signs and symptoms. Jugular venous distention (JVD) is the simplest and most reliable sign of fluid overload. Examination of the right internal jugular vein with the patient at a 45-degree angle is the preferred method for assessing JVD. The presence of JVD >4 cm above the sternal angle suggests systemic venous congestion. In patients with mild systemic congestion, JVD may be absent at rest, but application of pressure to the abdomen will cause an elevation of JVD (hepatojugular reflux).

Peripheral edema is a cardinal finding in heart failure. Edema usually occurs in dependent parts of the body, and thus is seen as ankle or pedal edema in ambulatory patients, although it may be manifested as sacral edema in bedridden patients. Adults typically have a 10 lb fluid weight gain before trace peripheral edema is evident; therefore, patients with acute decompensated heart failure may have no clinical evidence of systemic congestion except weight gain. Body weight is thus the best short-term end point for evaluating fluid status. Nonfluid weight gain and loss of muscle mass due to cardiac cachexia are potential confounders for long-term use of weight as a marker for fluid status. Hepatomegaly and ascites are other signs of systemic congestion.

Patients with heart failure may exhibit signs and symptoms of low cardiac output alone or in addition to volume overload. The primary complaint associated with such poor perfusion is fatigue. Patients may also complain of poor appetite or early satiety due to limited perfusion of the gastrointestinal (GI) tract. Conversely, patients with such GI complaints may simply be experiencing gut edema. More subjective measures of low cardiac output include worsening renal function, cool extremities, change in mental status, resting tachycardia, and narrow pulse pressure.

CLINICAL PRESENTATION OF HEART FAILURE

General

- Patient presentation may range from asymptomatic to cardiogenic shock.

Symptoms

- Dyspnea, particularly on exertion
- Orthopnea
- Paroxysmal nocturnal dyspnea
- Exercise intolerance
- Tachypnea
- Cough
- Fatigue
- Nocturia
- Hemoptysis
- Abdominal pain
- Anorexia
- Nausea
- Bloating
- Poor appetite, early satiety
- Ascites
- Mental status changes

Signs

- Pulmonary rales
- Pulmonary edema
- S_3 gallop
- Cool extremities
- Pleural effusion
- Cheyne-Stokes respiration
- Tachycardia
- Narrow pulse pressure
- Cardiomegaly
- Peripheral edema
- JVD
- Hepatojugular reflux
- Hepatomegaly

Laboratory Tests

- BNP >100 pg/mL
- Electrocardiogram may be normal, or it could show numerous abnormalities, including acute ST-T wave changes from myocardial ischemia, atrial fibrillation, bradycardia, and left ventricular hypertrophy.
- Serum creatinine may be increased due to hypoperfusion. Preexisting renal dysfunction can contribute to volume overload.
- Complete blood count (CBC) can be useful in determining if heart failure is due to a reduced oxygen-carrying capacity.

- Chest x-ray: useful for detecting cardiac enlargement, pulmonary edema, and pleural effusions
- Echocardiogram: used to assess the size of the left ventricle, valve function, pericardial effusion, wall motion abnormalities, and ejection fraction
- Hyponatremia: serum sodium <130 mEq/L is associated with reduced survival and may indicate worsening volume overload and/or disease progression.

DIAGNOSIS

No single test is available to confirm the diagnosis of heart failure—it is a clinical syndrome associated with specific signs and symptoms.[1,41] Because heart failure can be caused or worsened by multiple cardiac and noncardiac disorders, many of which may be treatable or reversible, accurate diagnosis is essential for development of therapeutic strategies. Heart failure is often initially suspected in a patient based on symptoms. These often include dyspnea, exercise intolerance, fatigue, and/or fluid retention. However, it must be emphasized that signs and symptoms lack sensitivity for diagnosing heart failure, as these symptoms are frequently found with many other disorders. Even in patients with known heart failure, there is a poor correlation between the presence or severity of symptoms and the hemodynamic abnormality.

A complete history and physical examination targeted at identifying cardiac or noncardiac disorders or behaviors that may cause or hasten heart failure development or progression are essential in the initial evaluation of a symptomatic patient. A careful medication history should also be obtained with a focus on use of ethanol, tobacco, illicit drugs (e.g., cocaine or methamphetamine), vitamins and supplements (including herbal or "natural" supplements), NSAIDs, and antineoplastic agents (anthracyclines, cyclophosphamide, trastuzumab, and imatinib).

Particular attention should be paid to cardiovascular risk factors and to other disorders that can cause or exacerbate heart failure, such as hypertension, diabetes, dyslipidemia, tobacco use, sleep-disordered breathing, and thyroid disease. Because coronary artery disease is the cause of heart failure in many patients, careful attention and evaluation of the possibility of coronary disease is essential, especially in men. If coronary artery disease is detected, appropriate revascularization procedures may then be considered. The patient's volume status should be documented by assessing the body weight, JVD, and presence or absence of pulmonary congestion and peripheral edema. Laboratory testing may assist in identification of disorders that cause or worsen heart failure. The initial evaluation should include a complete blood count, serum electrolytes (including calcium and magnesium), tests of renal and hepatic function, urinalysis, lipid profile, hemoglobin A1C, thyroid function tests, chest x-ray, and 12-lead electrocardiogram (ECG). There are no specific ECG findings associated with heart failure, but findings may help detect coronary artery disease or conduction abnormalities that could affect prognosis and guide treatment decisions. Measurement of BNP may also assist in differentiating dyspnea caused by heart failure from other causes.[25,26]

Although the history, physical examination, and laboratory tests provide important insight into the underlying cause of heart failure, the echocardiogram is the single most useful test in the evaluation of the patient. The echocardiogram is used to assess abnormalities in cardiac structure and function, including evaluation of the pericardium, myocardium, and heart valves, and to quantify the LVEF to determine if systolic or diastolic dysfunction is present.

TREATMENT OF SYSTOLIC HEART FAILURE

DESIRED OUTCOMES

The goals of therapy in the management of systolic heart failure are to improve the patient's quality of life, relieve or reduce symptoms, prevent or minimize hospitalizations for exacerbations of heart failure, slow progression of the disease process, and prolong survival. Although these goals are still important, identification of risk factors for heart failure development and recognition of its progressive nature have led to increased emphasis on preventing the development of this disorder. With this in mind, the American College of Cardiology/American Heart Association (ACC/AHA) guidelines for the evaluation and management of systolic heart failure utilize a staging system that not only recognizes the evolution and progression of the disorder, but also emphasizes risk factor modification and preventive treatment strategies.[1] The system is composed of four stages (Fig. 20–5). This staging system differs from the New York Heart Association (NYHA) functional classification (Table 20–4) with which most clinicians are familiar. The NYHA system is primarily intended to classify symptomatic heart failure according to the clinician's subjective evaluation and does not recognize preventive measures or the progression of the disorder. A patient's symptoms can change frequently over a short period of time due to changes in medications, diet, intercurrent illnesses, and so on. For example, a patient with ACC/AHA stage C heart failure with NYHA class IV symptoms such as marked volume overload could rapidly improve to class I or II with aggressive diuretic therapy. Despite these limitations, this system can be useful for monitoring patients and is widely used in heart failure studies. In contrast, and consistent with the progressive nature of heart failure, a patient's ACC/AHA heart failure stage could not improve (e.g., go from stage C to stage B) even though the patient's symptoms could fluctuate from NYHA class IV to I. In addition, the ACC/AHA staging system provides a more comprehensive framework for evaluation, prevention, and treatment of heart failure.

GENERAL MEASURES

The complexity of the heart failure syndrome necessitates a comprehensive approach to management that includes accurate diagnosis, identification, and treatment of risk factors, elimination or minimization of precipitating factors, appropriate pharmacologic and nonpharmacologic therapy, and close monitoring and follow-up.

The first step in management of systolic heart failure is to determine the etiology (see Table 20–1) and/or any precipitating factors. Treatment of underlying disorders such as hyperthyroidism may obviate the need for treatment of heart failure. Patients with valvular diseases may derive significant benefit from valve replacement or repair. Revascularization or anti-ischemic therapy in patients with coronary disease may reduce heart failure symptoms. Drugs that aggravate heart failure (see Table 20–3) should be discontinued if possible.

Restriction of physical activity reduces cardiac workload and is recommended for virtually all patients with acute congestive symptoms. However, once the patient's symptoms have stabilized, and excess fluid is removed, restrictions on physical activity are discouraged. Current guidelines support exercise training programs in stable patients with heart failure to improve clinical status.[1] More recently, exercise training in patients with left ventricular systolic dysfunction produced nonsignificant reductions in total mortality or hospitalization.[42]

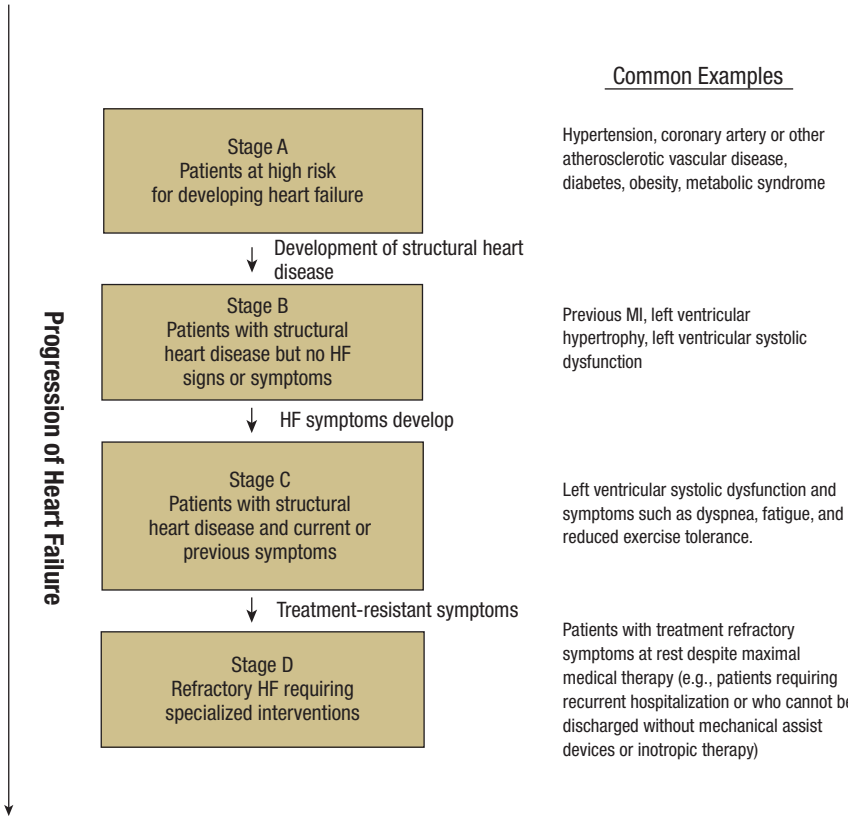

FIGURE 20-5. American College of Cardiology/American Heart Association (ACC/AHA) heart failure staging system. (HF, heart failure; MI, myocardial infarction.) *(Source: Hunt SA, Abraham WT, Chin MH, et al. 2009 focused update incorporated into the ACC/AHA 2005 Guidelines for the Diagnosis and Management of Heart Failure in Adults: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines: developed in collaboration with the International Society for Heart and Lung Transplantation. Circulation 2009;119:e391–e479.)*

Because a major compensatory response in heart failure is sodium and water retention, restriction of dietary sodium and fluid intake are important lifestyle interventions. Mild (<3 g per day) to moderate (<2 g per day) sodium restriction, in conjunction with daily measurement of weight, should be implemented to minimize volume retention and allow use of lower and safer diuretic doses. The typical American diet contains 8 to 10 g of sodium per day, so most patients would need to reduce their intake by approximately 50%. This can often be accomplished by not adding salt to prepared foods and eliminating foods high in sodium (e.g., salt-cured meats, salted snack foods, pickles, soups, delicatessen meats, and processed foods). In patients with hyponatremia (serum Na <130 mEq/L) or those with persistent volume retention despite high diuretic doses and sodium restriction, daily fluid intake should be limited to 2 L per day from all sources.

Other important general measures include patient and family counseling on the signs and symptoms of heart failure, detailed written instructions on the importance of appropriate medication use and compliance, activity level, diet, discharge medications, weight monitoring, and the need for close monitoring and follow-up to reinforce compliance and minimize the risk of heart failure exacerbations and subsequent hospitalization. These activities are now referred to as self-care and constitute an important means to improve such important outcomes as hospitalization and quality of life.[43]

TABLE 20-4 New York Heart Association Functional Classification

Functional class
I. Patients with cardiac disease but without limitations of physical activity. Ordinary physical activity does not cause undue fatigue, dyspnea, or palpitation.
II. Patients with cardiac disease that results in slight limitations of physical activity. Ordinary physical activity results in fatigue, palpitation, dyspnea, or angina.
III. Patients with cardiac disease that results in marked limitation of physical activity. Although patients are comfortable at rest, less than ordinary activity will lead to symptoms.
IV. Patients with cardiac disease that results in an inability to carry on physical activity without discomfort. Symptoms of congestive heart failure are present even at rest. With any physical activity, increased discomfort is experienced.

GENERAL APPROACH TO TREATMENT

4 Current ACC/AHA treatment guidelines are organized around the four identified stages of heart failure, and the treatment recommendations are summarized in Figures 20–6 and 20–7.[1] Clinicians are reminded that, in addition to the ACC/AHA, other cardiology professional societies have developed guidelines for evaluation and treatment of heart failure. The Heart Failure Society of America (HFSA) issued practice guidelines in 2006.[44] The HFSA and ACC/AHA guidelines are very similar with regard to care and treatment of patients with systolic heart failure. In addition, the HFSA guidelines provide a thorough discussion of other areas, including acute decompensated heart failure, heart failure with preserved LVEF, and management of patients with heart failure and a number of comorbid diseases. The HFSA guidelines will be periodically updated on the HFSA website (www.hfsa.org). Finally, the European Society of Cardiology (ESC) published guidelines for the management of both acute and systolic heart failure.[45] Although minor differences exist between the recommendations in the American and European guidelines, they are in general agreement in their overall approach. Clinicians caring for patients with heart failure should be familiar with these guidelines but should also remember that these indeed are only guidelines and that evaluation and treatment should be individualized for each patient.

Treatment of Stage A Heart Failure

Patients in stage A do not have structural heart disease or heart failure symptoms but are at high risk for developing heart failure because of the presence of risk factors (Fig. 20–6). The emphasis

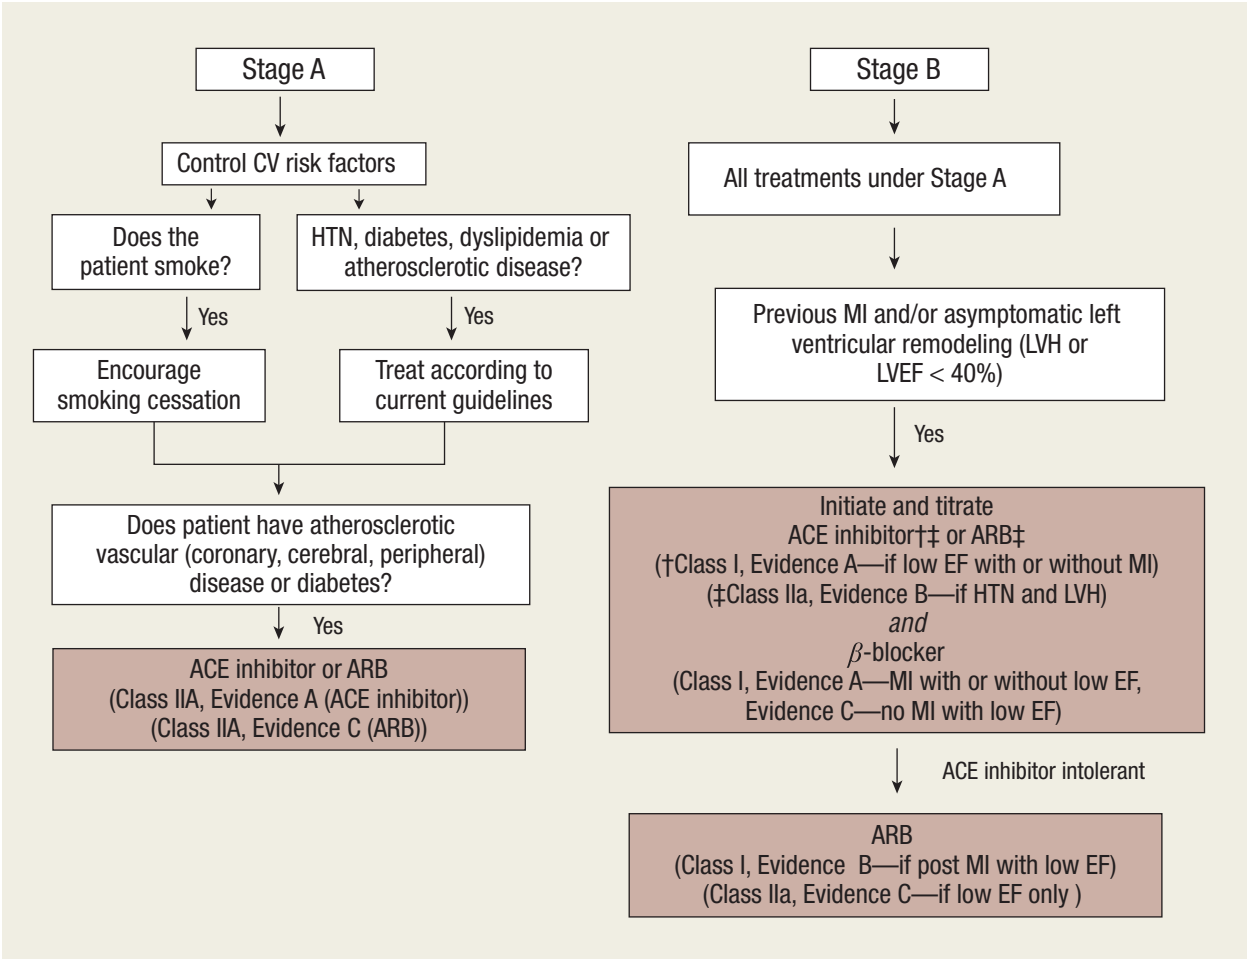

FIGURE 20-6. Treatment algorithm for patients with ACC/AHA stages A and B heart failure. (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; CV, cardiovascular; EF, ejection fraction; HTN, hypertension; LVEF, left ventricular ejection fraction; LVH, left ventricular hypertrophy; MI, myocardial infarction.) *(Source: Hunt SA, Abraham WT, Chin MH, et al. 2009 focused update incorporated into the ACC/AHA 2005 Guidelines for the Diagnosis and Management of Heart Failure in Adults: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines: developed in collaboration with the International Society for Heart and Lung Transplantation. Circulation 2009;119:e391–e479.)*

here is on identification and modification of these risk factors to prevent the development of structural heart disease and subsequent heart failure. Commonly encountered risk factors include hypertension, dyslipidemia, diabetes, obesity, metabolic syndrome, smoking, and coronary artery disease. Although each of these disorders individually increases risk, they frequently coexist in many patients and act synergistically to foster the development of heart failure. Effective control of both systolic and diastolic blood pressure reduces the risk of developing heart failure by approximately 50%; thus, current hypertension treatment guidelines should be followed.[36] Diabetes dramatically increases the risk of developing heart failure and adversely affects the prognosis of patients with known heart failure. Appropriate diabetic control is important to minimize the risk of end-organ damage but has not been shown to affect the risk of developing heart failure. Appropriate management of coronary disease and its associated risk factors is also important, including treatment of dyslipidemia and smoking cessation.[46] Although treatment must be individualized, ACE inhibitors or ARBs can be useful for antihypertensive therapy in patients with multiple vascular risk factors.[1] Adding further evidence that heart failure is a preventable disorder, a recent study found that such modifiable risk factors as body weight, smoking, exercise, alcohol intake, and consumption of fruits and vegetables reduced the lifetime risk of developing heart failure.[47]

Treatment of Stage B Heart Failure

Patients in stage B have structural heart disease but do not have heart failure symptoms (Fig. 20–6). This group includes patients with left ventricular hypertrophy, recent or remote MI, valvular disease, or reduced LVEF (less than 40%). These individuals are at risk for developing heart failure, and treatment is targeted at minimizing additional injury and preventing or slowing the remodeling process. In addition to the treatment measures outlined in stage A, ACE inhibitors and β-blockers are important components of therapy. Patients with a previous MI should receive both ACE inhibitors and β-blockers, regardless of the LVEF.[1] Similarly, patients with a reduced LVEF should also receive both of these agents, whether or not they have had an MI.[1] ARBs are an effective alternative in patients intolerant to ACE inhibitors.[1]

Treatment of Stage C Heart Failure

❹ ❺ ❻ ❼ ❽ ❾ ❿ Patients with structural heart disease and previous or current heart failure symptoms are classified as stage C (Fig. 20–7). In addition to treatments in stages A and B, most patients in stage C should be routinely treated with three medications: a diuretic, an ACE inhibitor, and a β-blocker (see Drug Therapies for Routine Use in Patients with Stage C Heart Failure).

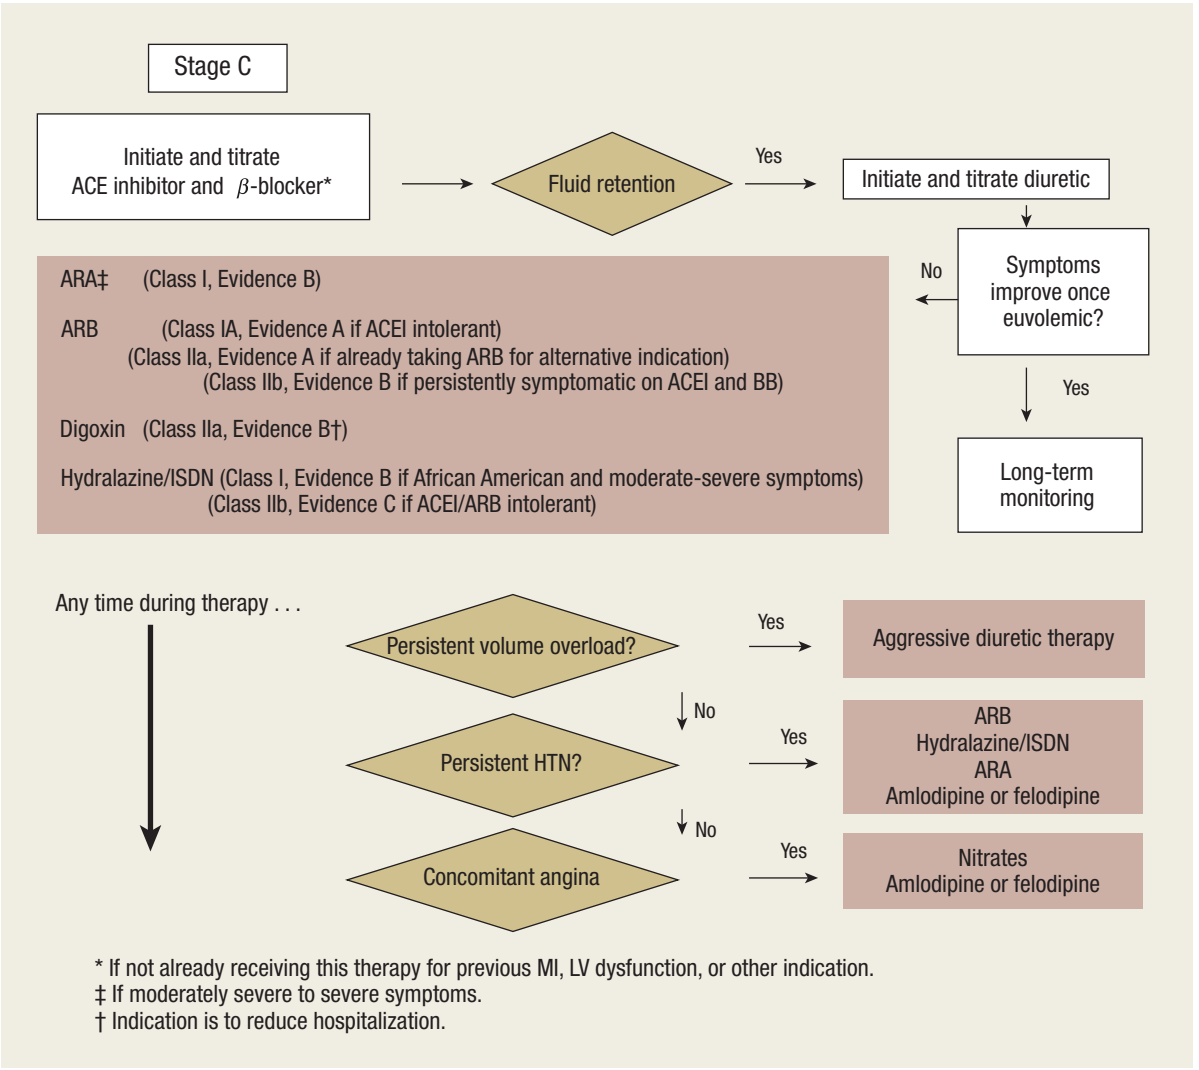

FIGURE 20-7. Treatment algorithm for patients with ACC/AHA stage C heart failure. (ACEI, angiotensin-converting enzyme I; ARA, aldosterone receptor antagonist; ARB, angiotensin receptor blocker; BB, β-blocker; HTN, hypertension; ISDN, isosorbide dinitrate; LV, left ventricular; MI, myocardial infarction.) *(Source: Hunt SA, Abraham WT, Chin MH, et al. 2009 focused update incorporated into the ACC/AHA 2005 Guidelines for the Diagnosis and Management of Heart Failure in Adults: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines: developed in collaboration with the International Society for Heart and Lung Transplantation. Circulation 2009;119:e391–e479.)*

The benefits of these medications on slowing heart failure progression, reducing morbidity and mortality, and improving symptoms are clearly established. Aldosterone receptor antagonists, ARBs, digoxin, and hydralazine-isosorbide dinitrate are also useful in selected patients. Nonpharmacologic therapy with devices such as an implantable cardiac defibrillator (ICD) or cardiac resynchronization therapy (CRT) with a biventricular pacemaker is also indicated in certain patients in stage C (see Nonpharmacologic Therapy). Other general measures are also important, including moderate sodium restriction, daily weight measurement, immunization against influenza and pneumococcus, modest physical activity, and avoidance of medications that can exacerbate heart failure. Recent evidence suggests that careful follow-up and patient education that reinforces dietary and medication compliance can prevent clinical deterioration and reduce hospitalization.[1,43]

Treatment of Stage D Heart Failure

Stage D heart failure includes patients with symptoms at rest that are refractory despite maximal medical therapy and those patients who undergo recurrent hospitalizations or cannot be discharged from the hospital without special interventions. These individuals have the most advanced form of heart failure and should be referred to heart failure management programs so that specialized therapies, including mechanical circulatory support, continuous intravenous (IV) positive inotropic therapy, and cardiac transplantation, can be considered in addition to standard treatments outlined in stages A, B, and C. A new continuous-flow left ventricular assist device was shown to improve outcomes with fewer adverse events compared with the traditional pulsatile-flow devices.[48] When no additional treatments are appropriate, discussions about prognosis and end of life care should be initiated.[1,49]

Management of volume status can be challenging in these patients. Restriction of sodium and fluid intake may be beneficial. High doses of diuretics, combination therapy with a loop and thiazide diuretic, or mechanical methods of fluid removal such as ultrafiltration may be required. Patients in stage D may be less tolerant to ACE inhibitors (hypotension, worsening renal insufficiency) and β-blockers (worsening heart failure), as circulatory homeostasis is maintained by high levels of neurohormonal activation. Initiation of

therapy with low doses, slow upward dose titration, and close monitoring for signs and symptoms of intolerance are essential in this group of patients. The approach to the treatment of patients with stage D heart failure is discussed in more detail in Chapter 22.

NONPHARMACOLOGIC THERAPY

Sudden cardiac death, primarily due to ventricular tachycardia and fibrillation, is responsible for 40% to 50% of the mortality in patients with heart failure. In general, patients in the earlier stages of heart failure with milder symptoms are more likely to experience sudden death, whereas death from pump failure is more frequent in those with advanced heart failure. Many of these patients have complex and frequent ventricular ectopy, although it remains unknown whether these ectopic beats contribute to the risk of malignant arrhythmias or merely serve as markers for individuals at higher risk for sudden death. Drugs that attenuate disease progression such as β-blockers and aldosterone antagonists reduce the risk of sudden death. However, empiric treatment with class I antiarrhythmic agents, although they can suppress ventricular ectopy, adversely affects survival.[50]

Amiodarone is reported to have a neutral effect on survival in patients with heart failure and low LVEF. The role of the ICD compared with amiodarone for primary prevention of sudden death was evaluated in Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT). The ICD was superior to amiodarone or placebo for reducing mortality in patients with NYHA class II or III symptoms and LVEF ≤35%, regardless of the etiology of heart failure.[51] Importantly, this study also found that amiodarone had no benefit compared with placebo; thus, this drug, because of its multiple adverse effects, drug interactions, and lack of effect on mortality, should not be used for primary prevention of sudden death. However, because of the neutral effects of amiodarone on survival, it is often used in patients with symptomatic atrial fibrillation to maintain sinus rhythm and/or to prevent ICD discharges. Thus, the ACC/AHA guidelines recommend the ICD for both primary and secondary prevention to improve survival in patients with current or previous heart failure symptoms and reduced LVEF.[1] A thorough review of ICD therapy can be found in Chapter 25.

Recent studies demonstrate that CRT offers a promising approach to select patients with systolic heart failure.[52,53] Delayed electrical activation of the left ventricle, characterized on the ECG by a QRS duration that exceeds 120 msec, occurs in approximately one third of patients with moderate to severe systolic heart failure. Because the left and right ventricles normally activate simultaneously, this delay results in asynchronous contraction of the ventricles, which contributes to the hemodynamic abnormalities of heart failure. Implantation of a specialized biventricular pacemaker to restore synchronous activation of the ventricles can improve ventricular contraction and hemodynamics. Use of CRT is associated with improvements in exercise capacity, NYHA classification, quality of life, hemodynamic function, hospitalizations, and mortality.[52,53] Current guidelines indicate CRT should be used only in NYHA class III and IV patients receiving optimal medical therapy and with a QRS duration ≥120 msec and LVEF ≤35%. However, the recently published Multicenter Automatic Defibrillator Implantation Trial with Cardiac Resynchronization Therapy (MADIT-CRT) trial found that the combination of CRT plus an ICD reduced death or heart failure events by 34% compared with an ICD alone in patients with an LVEF ≤30% and a QRS duration ≥130 msec and less severe symptoms (NYHA class I or II).[54] This earlier use of CRT is also associated with reverse remodeling.[55] It remains to be determined if these new data will result in changes to the guidelines. Combined CRT and ICD devices are available and can be used if the patient meets the indications for both devices.

PHARMACOLOGIC THERAPY

Drug Therapies for Routine Use in Patients with Stage C Heart Failure

4 5 6 7 A treatment algorithm for management of patients with stage C heart failure is shown in Figure 20–7. In general, these patients should receive combined therapy with an ACE inhibitor or ARB and a β-blocker, plus a diuretic if there is evidence of fluid retention. Initiation of digoxin therapy can be considered at any time for symptom reduction, to decrease hospitalizations, or to slow ventricular response in patients with concomitant atrial fibrillation.[1] An aldosterone receptor antagonist should also be considered in select patients.[1]

Diuretics 7 The compensatory mechanisms in heart failure stimulate excessive sodium and water retention, often leading to pulmonary and systemic congestion.[56,57] Diuretic therapy, in addition to sodium restriction, is recommended in all patients with clinical evidence of fluid retention. Once fluid overload has been resolved, many patients require chronic diuretic therapy to maintain euvolemia. Among the drugs used to manage heart failure, diuretics are the most rapid in producing symptomatic benefits. However, diuretics do not prolong survival or (with the possible exception of torsemide) alter disease progression, and therefore are not considered mandatory therapy. Thus, patients who do not have fluid retention would not require diuretic therapy.

The primary goal of diuretic therapy is to reduce symptoms associated with fluid retention, improve exercise tolerance and quality of life, and reduce hospitalizations from heart failure. They accomplish this by decreasing pulmonary and peripheral edema through reduction of preload. Although preload is a determinant of cardiac output, the Frank-Starling curve (see Fig. 20–3) shows that patients with congestive symptoms have reached the flat portion of the curve. A reduction in preload improves symptoms but has little effect on the patient's stroke volume or cardiac output until the steep portion of the curve is reached. However, diuretic therapy must be used judiciously because overdiuresis can lead to a reduction in cardiac output, renal perfusion, and symptoms of dehydration.

Diuretic therapy is usually initiated in low doses in the outpatient setting, with dosage adjustments based on symptom assessment and daily body weight. Change in body weight is a sensitive marker of fluid retention or loss, and it is recommended that patients monitor their status by taking daily morning body weights. Patients who gain 1 lb per day for several consecutive days or 3 to 5 lb in a week should contact their healthcare provider for instructions (which often will be to increase the diuretic dose temporarily). Such action often will allow patients to prevent a decompensation that requires hospitalization. One study demonstrated a significant reduction in emergency department visits with a protocol that directed patients to self-adjust their diuretic dose based on changes in heart failure symptoms and daily body weight.[58] Hypotension or worsening renal function (e.g., increases in serum creatinine) may be indicative of volume depletion and necessitate a reduction in the diuretic dose. Assessing volume status is particularly important before ACE inhibitor or β-blocker initiation or dose uptitration, as overdiuresis may predispose patients to hypotension and other adverse effects with increases in ACE inhibitor or β-blocker doses.

Thiazide diuretics Thiazide diuretics such as hydrochlorothiazide block sodium reabsorption in the distal convoluted tubule (~5–8% of filtered sodium). The thiazides therefore are relatively weak diuretics and infrequently are used alone in heart failure. However, thiazides or the thiazide-like diuretic metolazone can be used in combination with loop diuretics to promote a very effective diuresis. In addition, thiazide diuretics may be preferred in patients with only mild fluid

TABLE 20-5 Loop Diuretics: Use in Heart Failure

	Furosemide	Bumetanide	Torsemide
Usual daily dose (po)	20–160 mg/d	0.5–4 mg/d	10–80 mg/d
Ceiling dose[a]			
Normal renal function	80-160 mg	1–2 mg	20-40 mg
CL_{CR} 20–50 mL/min	160 mg	2 mg	40 mg
CL_{CR} <20 mL/min	400 mg	8–10	100 mg
Bioavailability	10–100% Average: 50%	80–90%	80–100%
Affected by food	Yes	Yes	No
Half-life	0.3–3.4 h	0.3–1.5 h	3–4 h

[a] Ceiling dose: single dose above which additional response is unlikely to be observed.

retention and elevated blood pressure because of their more persistent antihypertensive effects compared with loop diuretics.

Loop diuretics Loop diuretics are usually necessary to restore and maintain euvolemia in heart failure. They act by inhibiting a Na-K-2Cl transporter in the thick ascending limb of the loop of Henle, where 20% to 25% of filtered sodium normally is reabsorbed. Because loop diuretics are highly bound to plasma proteins, they are not highly filtered at the glomerulus. They reach the tubular lumen by active transport via the organic acid transport pathway. Competitors for this pathway (probenecid or organic by-products of uremia) can inhibit delivery of loop diuretics to their site of action and decrease effectiveness. Loop diuretics also induce a prostaglandin-mediated increase in renal blood flow, which contributes to their natriuretic effect. Coadministration of NSAIDs blocks this prostaglandin-mediated effect and can diminish diuretic efficacy. Excessive dietary sodium intake may also reduce the efficacy of loop diuretics. Unlike thiazides, loop diuretics maintain their effectiveness in the presence of impaired renal function, although higher doses may be necessary to obtain adequate delivery of the drug to the site of action.

Heart failure is one of the disease states in which the maximal response to loop diuretics is reduced. This is believed to result from a decrease in the rate of diuretic absorption and/or increased proximal or distal tubule reabsorption of sodium, possibly due to increased activity of the Na-K-2Cl transporter.[56] As a consequence, doses above the recommended ceiling produce no additional diuresis. Thus, once the ceiling dose is reached, it is recommended that more frequent doses be given for additional effect rather than progressively higher doses. The appropriate chronic dose of a loop diuretic is that which maintains the patient at a stable dry weight without symptoms of dyspnea. Ranges of doses of loop diuretics and recommended ceiling doses are shown in Table 20–5.

ACE Inhibitors 5 ACE inhibitors are the cornerstone of pharmacotherapy for patients with heart failure. By blocking the conversion of angiotensin I to angiotensin II by ACE, the production of angiotensin II and, in turn, aldosterone is decreased, but not completely eliminated.[17] This decrease in angiotensin II and aldosterone attenuates many of the deleterious effects of these neurohormones, including ventricular remodeling, myocardial fibrosis, myocyte apoptosis, cardiac hypertrophy, norepinephrine release, vasoconstriction, and sodium and water retention.[17] Thus, ACE inhibitor therapy plays an important role in preventing RAAS-mediated progressive worsening of myocardial function. The endogenous vasodilator bradykinin, which is inactivated by ACE, is also increased by ACE inhibitors, along with the release of vasodilatory prostaglandins and histamine.[17] The precise contribution of the effects of ACE inhibitors on bradykinin and vasodilatory prostaglandins is unclear. However, the persistence of clinical benefits with ACE inhibitors despite the fact that angiotensin II and aldosterone levels return to pretreatment levels in some patients suggests this is a potentially important effect.[17]

Numerous placebo-controlled clinical trials involving over 7,000 patients with reduced LVEF have documented the favorable effects of ACE inhibitor therapy on symptoms, NYHA functional classification, clinical status, exercise tolerance, and quality of life.[17] When compared with placebo, patients treated with ACE inhibitors have fewer treatment failures, hospitalizations, and increases in diuretic dosages.[17]

More importantly, these trials show that ACE inhibitors improve survival by 20% to 30% compared with placebo and that these benefits are maintained for years after therapy is initiated.[17] In addition to improving survival, ACE inhibitors reduce the combined risk of death or hospitalization, slow the progression of heart failure, and reduce the rates of reinfarction.[17] The benefits of ACE inhibitor therapy are independent of the etiology of heart failure (ischemic vs nonischemic) and are observed in patients with mild, moderate, or severe symptoms.

ACE inhibitors also are effective for preventing the development of heart failure and reducing cardiovascular risk. Enalapril decreases the risk of hospitalization for worsening heart failure and reduces the composite end point of death and heart failure hospitalization in patients with asymptomatic left ventricular dysfunction.[59] In patients with established atherosclerotic vascular disease (e.g., coronary, cerebral, or peripheral circulations) and normal LVEF, ACE inhibitors reduce the development of new-onset heart failure and diabetes, cardiovascular death, overall mortality, MI, and stroke.[60]

The most common cause of heart failure is ischemic heart disease, where MI results in loss of myocytes, followed by ventricular dilation and remodeling. Captopril, ramipril, and trandolapril have all been shown to benefit patients following MI whether they are initiated early (within 36 hours) and continued for 4 to 6 weeks or started later and administered for several years.[17] Collectively, these studies indicate that ACE inhibitors after MI improve overall survival, decrease development of severe heart failure, and reduce reinfarction and heart failure hospitalization rates.[17] The effects are most pronounced in higher-risk patients, such as those with symptomatic heart failure or reduced LVEF, with 20% to 30% reductions in mortality reported in these patients.[17] Post-MI patients without heart failure symptoms or decreases in LVEF (stage B) should also receive ACE inhibitors to prevent the development of heart failure and to reduce mortality.[1,17]

The clear benefit of ACE inhibitors is evident in the Joint Commission for Accreditation of Healthcare Organizations (JCAHO) and Centers for Medicare and Medicaid Services (CMS) selection of ACE inhibitor use in patients with heart failure and decreased LVEF as a key performance measure. This measure states that patients with left ventricular systolic dysfunction discharged from the hospital should receive ACE inhibitors unless there is documentation in the medical record of an absolute contraindication or drug intolerance. Despite the overwhelming benefit demonstrated with these agents, they remain underused and underdosed.[61] Also, for patients receiving an ACE inhibitor at hospital discharge, use significantly decreases over time, and patients not prescribed ACE inhibitors at discharge were unlikely to have therapy initiated in the outpatient setting.[61] Common reasons cited for underuse or underdosing are concerns about safety and adverse reactions to ACE inhibitors, especially in patients with underlying renal dysfunction or hypotension.

The use of ACE inhibitors in patients with renal insufficiency is particularly relevant, as it is present in 25% to 50% of patients with heart failure and is associated with an increased risk of mortality.[62] Despite the perceived risks, recent data indicate that ACE inhibitors may be more effective in those patients with renal insufficiency.[63,64] Because many patients with heart failure have concomitant disorders (e.g., diabetes, hypertension, and previous MI) that also may be favorably affected by ACE inhibitors, renal dysfunction should

not be an absolute contraindication to ACE inhibitor use in patients with left ventricular dysfunction. However, these patients should be monitored carefully for the development of worsening renal function and/or hyperkalemia with special attention to risk factors associated with this complication of ACE inhibitor therapy.[1]

An important practical consideration is determining the proper dose of an ACE inhibitor. The ability to achieve target doses shown to be effective in clinical trials may be limited by hypotension and/or a decline in renal function. Clinical trials establishing the efficacy of these agents titrated drug doses to a predetermined target rather than according to therapeutic response. Although data on the dose-dependent effects of ACE inhibitors in patients with heart failure are limited, higher doses may reduce the risk of hospitalization compared with lower doses, but there do not appear to be significant differences in mortality.[65] In many positive trials of other heart failure therapies (e.g., β-blockers and aldosterone antagonists), intermediate ACE inhibitor doses were generally used as background therapy. These results emphasize that clinicians should attempt to use ACE inhibitor doses proven beneficial in clinical trials, but if these doses are not tolerated, lower doses can be used with the knowledge that there are likely only small differences in mortality outcomes between the high and low doses. Also, initiation of β-blocker therapy should not be delayed until target ACE inhibitor doses are achieved, because the addition of a β-blocker is proven to reduce mortality, whereas that is not the case with increasing ACE inhibitor doses.

In summary, the evidence that ACE inhibitors improve symptoms, slow disease progression, and decrease mortality in patients with heart failure and reduced LVEF (stage C) is unequivocal. Current guidelines indicate these patients should receive ACE inhibitors, unless contraindications are present.[1]

Beta-Blockers 6 There is overwhelming evidence from multiple randomized, placebo-controlled clinical trials that β-blockers reduce morbidity and mortality in patients with heart failure. As such, the ACC/AHA guidelines on the management of heart failure recommend that β-blockers should be used in all stable patients with heart failure and a reduced LVEF in the absence of contraindications or a clear history of β-blocker intolerance.[1] Patients should receive a β-blocker even if their symptoms are mild or well controlled with diuretic and ACE inhibitor therapy. Importantly, it is not essential that ACE inhibitor doses are optimized before a β-blocker is started because the addition of a β-blocker is likely to be of greater benefit than an increase in ACE inhibitor dose.[1] Beta-blockers are also recommended for asymptomatic patients with a reduced LVEF (stage B) to decrease the risk of progression to heart failure.

Beta-blockers have been studied in over 20,000 patients with heart failure in placebo-controlled trials. Three β-blockers have been shown to significantly reduce mortality compared with placebo: carvedilol, metoprolol CR/XL, and bisoprolol. Each was studied in a large population with the primary end point of mortality. Carvedilol was the first β-blocker shown to improve survival in heart failure. In the U.S. Carvedilol Heart Failure Study, 1,094 patients were randomized to carvedilol or placebo in addition to standard therapy, including an ACE inhibitor, digoxin, and diuretic.[66] The study was stopped early because of a 65% reduction in the risk of death with carvedilol. Nearly 4,000 patients were randomized to metoprolol CR/XL (Toprol XL) or placebo in the Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure (MERIT-HF), the largest β-blocker mortality trial to date.[67] This trial was also stopped early because of a significant survival benefit with β-blockade. Specifically, metoprolol was associated with a 34% reduction in total mortality, a 41% reduction in sudden death, and a 49% reduction in death from worsening heart failure. Bisoprolol was studied in over 2,600 patients enrolled in the Cardiac Insufficiency Bisoprolol Study II (CIBIS II).[68] This study was also stopped prematurely because of a 34% reduction in total mortality with bisoprolol compared with placebo. Bisoprolol was associated with a 44% reduction in sudden death and a 26% reduction in death due to worsening heart failure. Multiple post hoc subgroup analyses of data from the MERIT-HF and CIBIS II trials suggest that the benefits of β-blockade occur regardless of heart failure etiology or disease severity.

The majority of participants in MERIT-HF and CIBIS II had either NYHA class II or class III heart failure, and β-blockers became standard therapy in patients with class II or III disease after these trials were published. However, the efficacy and safety of β-blockers in patients with class IV heart failure were unclear until publication of the Carvedilol, Prospective, Randomized, Cumulative Survival (COPERNICUS) trial.[69] This trial randomized nearly 2,300 clinically stable patients who had symptoms at rest or with minimal exertion to carvedilol or placebo. Like the other studies, COPERNICUS was stopped prematurely after carvedilol produced a 35% relative reduction in mortality. Carvedilol was well tolerated in this population, with fewer participants receiving carvedilol compared with placebo requiring permanent discontinuation of study medication.

Data supporting the use of β-blockers in asymptomatic patients with left ventricular systolic dysfunction (stage B) come from a study of carvedilol in post-MI patients with a decreased LVEF.[70] Although the primary end point of all-cause mortality or hospital admission for cardiovascular problems was similar in the carvedilol and placebo groups, carvedilol significantly reduced all-cause mortality alone compared with placebo. Cardiovascular mortality and nonfatal MI were also lower among carvedilol-treated patients.

In addition to improving survival, β-blockers have been shown to improve multiple other end points. All the large clinical trials demonstrated 15% to 20% reductions in all-cause hospitalization and 25% to 35% reductions in hospitalizations for worsening heart failure with β-blocker therapy.[68,71,72] Studies have also shown consistent improvements in left ventricular systolic function with β-blockers, with increases in LVEF of 5 to 10 units (e.g., from an EF of 20% to 25% or 30%) after several weeks to months of therapy. Beta-blockers have also been shown to decrease ventricular mass, improve the sphericity of the ventricle, and reduce systolic and diastolic volumes (left ventricular end-systolic volume and left ventricular end-diastolic volume).[73,74] These effects are often collectively called *reverse remodeling,* referring to the fact that they return the heart toward more normal size, shape, and function.

The effects of β-blockers on symptoms and exercise tolerance varied among studies. Many studies showed improvements in NYHA functional class, patient symptom scores or quality-of-life assessments (e.g., the Minnesota Living with Heart Failure Questionnaire), and exercise performance, as assessed by the 6-minute walk test.[71–73] Other investigators found significant reductions in mortality with β-blockers but no significant improvement in symptoms.[75] As such, it is important to educate patients that β-blocker therapy is expected to positively influence disease progression and survival even if there is little to no symptomatic improvement.

The majority of participants in β-blocker trials were on ACE inhibitors at baseline because the benefits of ACE inhibitors were proven prior to β-blocker trials. Whether the strategy of starting a β-blocker prior to an ACE inhibitor is safe and effective has been debated. This issue was addressed in CIBIS III, in which patients with mild to moderate symptoms were randomized to initial therapy with either bisoprolol or enalapril.[76] Rates of death or hospitalization were similar with the two strategies. However, the trial failed to satisfy the prespecified statistical criterion for noninferiority of initial therapy with a β-blocker compared with an ACE inhibitor. In the absence of more compelling evidence, ACE inhibitors should be started first in most patients. Initiating a β-blocker first may be advantageous for patients with evidence of excessive SNS activity (e.g., tachycardia)

and may also be appropriate for patients whose renal function or potassium concentrations preclude starting an ACE inhibitor (or ARB) at that time. However, the risk for decompensation during β-blocker initiation may be greater in the absence of preexisting ACE inhibitor therapy, and careful monitoring is essential.

Beta-blockers antagonize the detrimental effects of the SNS described earlier in the chapter. To this end, potential mechanisms to explain the favorable effects of β-blockers in heart failure include antiarrhythmic effects, attenuating or reversing ventricular remodeling, decreasing myocyte death from catecholamine-induced necrosis or apoptosis, preventing fetal gene expression, improving left ventricular systolic function, decreasing heart rate and ventricular wall stress, thereby reducing myocardial oxygen demand, and inhibiting plasma renin release.[1]

Components that are critical for successful β-blocker therapy include appropriate patient selection, drug initiation and titration, and patient education. Beta-blockers should be initiated in stable patients who have no or minimal evidence of fluid overload.[1] Although β-blockers are typically started in the outpatient setting, there are data indicating that initiation of a β-blocker prior to discharge in patients who are hospitalized for decompensated heart failure increases β-blocker usage compared with outpatient initiation without increasing the risk of serious adverse effects.[77] However, β-blockers should not be started in patients who are hospitalized in the intensive care unit or recently required IV inotropic support. In unstable patients, other heart failure therapy should be optimized and then β-blocker therapy reevaluated once stability is achieved.

Initiation of a β-blocker at normal doses in patients with heart failure may to lead to symptomatic worsening or acute decompensation owing to the drug's negative inotropic effect. For this reason, β-blockers are listed as drugs that may exacerbate or worsen heart failure (see Table 20–3). To minimize the likelihood of acute decompensation, β-blockers should be started in very low doses with slow upward dose titration. The starting doses and target doses achieved in clinical trials are described in Table 20–6. Of note, the smallest commercially available tablet of bisoprolol is a scored 5 mg tablet. Because the recommended starting dose of 1.25 mg/day is not readily available, bisoprolol is the least commonly used of the three agents and, in fact, is not approved by the FDA for use in heart failure. Thus, therapy is generally limited to either carvedilol or metoprolol CR/XL, and there is no compelling evidence that one drug is superior to the other. A controlled-release formulation of carvedilol (carvedilol CR) that allows once-daily dosing is available, and pharmacokinetic studies demonstrate similar degrees of drug exposure with the controlled- and immediate-release formations of the drug.[78] There are data showing similar adherence rates with the once- and twice-daily formulations of carvedilol.[79] Nonetheless, carvedilol CR may be considered in patients with difficulty maintaining adherence to the immediate-release formulation.

TABLE 20-6 Initial and Target Doses for β-blockers Used in Treatment of Heart Failure

Drug	Initial Dose[b]	Target Dose
Bisoprolol[a]	1.25 mg once daily	10 mg once daily
Carvedilol[a]	3.125 mg bid	25 mg bid[c]
Carvedilol CR	10 mg once daily	80 mg once daily
Metoprolol succinate CR/XL[a]	12.5–25 mg once daily[d]	200 mg once daily

[a] Regimens proven in large trials to reduce mortality.
[b] Doses should be doubled approximately every 2 weeks, or as tolerated by the patient, until the highest tolerated or target dose is reached.
[c] Target dose for patients >85 kg is 50 mg bid.
[d] In MERIT-HF, the majority of NYHA class II patients were given 25 mg once daily, while the majority of class III patients were given 12.5 mg once daily as their starting dose.

Beta-blocker doses should be doubled no more often than every 2 weeks, as tolerated, until the target or maximally tolerated dose is reached. According to current guidelines, target doses are those associated with reductions in mortality in placebo-controlled clinical trials.[1] Data with both metoprolol and carvedilol suggest that heart rate may serve as a guide to the degree of β-blockade and that lower β-blocker doses might be considered reasonable if the reduction in heart rate indicates a good response to β-blocker therapy.[80] In fact, it remains uncertain whether β-blocker dose or the degree of heart rate reduction is the optimal end point to guide dose—titration and predict survival.

A recent meta-analysis of 23 randomized trials involving over 19,000 patients receiving β-blockers for heart failure compared heart rate reduction and β-blocker dose as predictors of survival.[80] Overall, β-blocker treatment was associated with a 24% mortality reduction. However, trials with the largest decrease in heart rate (median 15 beats/min) reported a 36% reduction in mortality, whereas trials with the smallest heart rate reduction (median 8 beats/min) showed only a 9% mortality reduction. Greater magnitude of heart rate reduction was significantly associated with greater improvement in survival. On the other hand, no relationship between β-blocker dose and magnitude of mortality decrease was found. The results from this study suggest that the degree of β-blocker-mediated reduction in resting heart rate, but not β-blocker dose, is associated with the magnitude of improved survival. However, the analysis is limited by its retrospective design, inability to account for other factors affecting heart rate (e.g., vagal activity, β-receptor pharmacogenomics) and reliance on resting heart rate as a surrogate marker for the extent of β-blockade. Although resting heart rate is routinely used clinically to evaluate the extent of β-blockade, it is not as accurate as inhibition of exercise heart rate. Whether magnitude of resting heart rate reduction or achievement of clinical trial doses is the optimal surrogate marker for improved outcomes with β-blockers in heart failure remains uncertain and may only be definitively determined by prospective trials.

Good communication between the patient and healthcare provider(s) is particularly important for successful therapy. Patients should understand that dose uptitration is a long, gradual process and that achieving the target dose is important to maximize the benefits of therapy. Patients should also be aware that response to therapy may be delayed and that heart failure symptoms may actually worsen during the initiation period. In the event of worsening symptoms, patients who understand the potential benefits of long-term β-blocker therapy may be more likely to continue treatment.

In summary, the data provide clear evidence that β-blockers slow disease progression, decrease hospitalizations, and improve survival in heart failure. Beta-blockers have also been shown to improve quality of life in many patients with heart failure, although this is not a universal finding. Based on these data, β-blockers are recommended as standard therapy for all patients with systolic dysfunction, regardless of the severity of their symptoms. Clinical trial experience shows that target β-blocker doses can be achieved in the majority of patients provided that appropriate initiation, titration, and education are implemented.

Drug Therapies to Consider for Select Patients

Angiotensin II Receptor Blockers 5 The crucial role of the RAAS in heart failure development and progression is well established, as are the benefits of inhibiting this system with ACE inhibitors. Despite the efficacy of ACE inhibitors, heart failure still progresses in many patients. ACE inhibitors decrease angiotensin II production in the short term, but these agents do not completely suppress generation of this hormone. With chronic administration of ACE inhibitors, ACE escape, characterized by increases

in circulating angiotensin II and aldosterone, often occurs.[81] In addition, angiotensin II can be formed in a number of tissues, including the heart, through non-ACE-dependent pathways (e.g., chymase, cathepsin, and kallikrein).[17,81] Therefore, blockade of the detrimental effects of angiotensin II by ACE inhibition is incomplete. In addition, troublesome adverse effects of ACE inhibitors such as cough are linked to accumulation of bradykinin.[17] The ARBs block the angiotensin II receptor subtype, AT_1, preventing the deleterious effects of angiotensin II, regardless of its origin. Because ARBs do not inhibit the ACE enzyme, these agents do not appear to affect bradykinin.[81] By inhibiting both the formation of angiotensin II and its effects on the AT_1 receptor, combination therapy with an ACE inhibitor plus an ARB offers a theoretical advantage over either agent used alone through more complete blockade of the deleterious effects of angiotensin II. Also, by directly blocking AT_1 receptors, ARBs would allow unopposed stimulation of AT_2 receptors, causing vasodilation and inhibition of ventricular remodeling.[81] Because bradykinin-related adverse effects of ACE inhibitors such as angioedema and cough lead to drug discontinuation in some patients, the potential for an ARB to produce similar clinical benefits with fewer side effects is of great interest. Whether ARBs add incremental benefit to current established therapies or are superior (or equivalent) to ACE inhibitors is the focus of several clinical trials.[81]

Although a number of ARBs are currently available, the primary clinical trials supporting the use of these agents in heart failure used either valsartan or candesartan.[81] The Valsartan Heart Failure Trial (Val-HeFT) evaluated whether the addition of valsartan to standard background heart failure therapy (which included an ACE inhibitor in 93% and a β-blocker in 35% of patients) improved survival.[82] The addition of valsartan had no effect on all-cause mortality but produced a 13% reduction in morbidity and mortality (principally due to reductions in heart failure hospitalizations). Based on these results, valsartan is now approved for use in patients with NYHA class II to IV heart failure. The Valsartan in Acute Myocardial Infarction (VALIANT) trial compared the effect of valsartan, captopril, and the combination of the two agents in post-MI patients with symptomatic heart failure, reduced left ventricular systolic function, or both in a noninferiority trial design.[83] There were no differences in the primary end point of total mortality between patients receiving valsartan and captopril, captopril alone, or valsartan alone. Thus, in this high-risk post-MI population, valsartan was as effective as captopril in reducing the risk of death, but combination therapy only increased the risk of adverse effects and did not improve survival compared to monotherapy with either agent. Based on these findings, valsartan is now approved for use in post-MI patients with left ventricular failure or left ventricular dysfunction.

The Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity (CHARM) trials were designed as three studies to evaluate candesartan in patients with symptomatic heart failure.[84] Both the CHARM-Added (patients receiving background ACE inhibitor therapy)[85] and CHARM-Alternative (patients intolerant of ACE inhibitor therapy)[86] trials found significant reductions in the primary end point of cardiovascular death or hospitalization for heart failure in patients receiving candesartan, although the benefit was modest in CHARM-Added (17% reduction). No significant benefit of candesartan was observed in CHARM-Preserved (patients with LVEF >40%).[87] Overall, candesartan was well tolerated, but its use was associated with an increased risk of hypotension, hyperkalemia, and renal dysfunction. On the basis of these results, candesartan is now approved for use in symptomatic heart failure in patients with LVEF ≤40% to reduce cardiovascular death and reduce heart failure hospitalizations. These benefits are present when candesartan is used alone or with an ACE inhibitor.

The effect of high-dose compared with low-dose losartan treatment was evaluated in the Heart Failure Endpoint Evaluation of Angiotensin II Antagonist Losartan (HEAAL) study.[88] Over 3,800 patients who were intolerant to ACE inhibitors with an LVEF ≤40% and NYHA class II to IV symptoms were randomly assigned to losartan 50 or 150 mg daily. The primary end point was a composite of death or heart failure admission, and all patients received standard background heart failure pharmacotherapy. The higher losartan dose was associated with significant reductions (~10%) in the primary end point. Significant increases in renal insufficiency, hyperkalemia, and hypotension were also associated with the higher dose, but the development of these adverse effects did not result in increased rates of drug discontinuation. Although losartan is not approved for the treatment of heart failure, these results suggest that incremental benefit can be achieved by increasing doses of ARBs and ACE inhibitors[65] to achieve higher degrees of RAAS inhibition.

Although ACE inhibitors remain first-line therapy in patients with stage C heart failure and reduced LVEF, the current ACC/AHA guidelines recommend the use of ARBs in patients who are unable to tolerate ACE inhibitors.[1] Similarly, ARBs are alternatives to ACE inhibitors in patients with stage A or B heart failure.[1] Cough and angioedema are the most common causes of ACE inhibitor intolerance. Caution should be exercised when ARBs are used in patients with angioedema from ACE inhibitors, as some cross-reactivity has been reported.[89,90] ARBs are not an alternative in patients with hypotension, hyperkalemia, or renal insufficiency secondary to ACE inhibitors because they are as likely to cause these adverse effects. Also, the combined use of ACE inhibitors, ARBs, and aldosterone antagonists is not recommended because of the increased risk of renal dysfunction and hyperkalemia.[1] The specific drugs and doses proven to be effective in clinical trials should be used.

The role of combination therapy with an ACE inhibitor and an ARB remains controversial. The CHARM-Added trial found the addition of candesartan to ACE inhibitor and β-blocker therapy produced incremental reductions in cardiovascular death and hospitalizations for heart failure but did not improve overall survival.[85] In contrast, neither the VALIANT nor the Val-HeFT trials found additional benefit from the addition of valsartan to ACE inhibitor treatment.[82,83] Moreover, a recent meta-analysis showed that combination therapy is associated with increased risk of medication discontinuation due to adverse effects, hyperkalemia, renal insufficiency, and hypotension.[91] Collectively, these results suggest the addition of an ARB to optimal heart failure therapy (ACE inhibitors, β-blockers, diuretics, etc.) offers, at best, marginal benefits with increased risk of adverse effects. The current guidelines indicate that the addition of an ARB can be considered in patients who remain symptomatic despite receiving conventional heart failure pharmacotherapy. Some clinicians suggest that the addition of an aldosterone antagonist to ACE inhibitor and β-blocker therapy is preferred over that of an ARB. The proven survival benefit of aldosterone antagonists in patients with NYHA class III or IV heart failure (RALES trial) and in post-MI patients with left ventricular systolic dysfunction (EPHESUS trial), as discussed in the following section, supports this approach.[22,23]

Aldosterone Antagonists ❾ Spironolactone and eplerenone are aldosterone antagonists that work by blocking the mineralocorticoid receptor, the target site for aldosterone. In the kidney, aldosterone antagonists inhibit sodium reabsorption and potassium excretion. Although the diuretic effects with low doses of aldosterone antagonists are minimal, the potassium-sparing effects can have significant consequences, as discussed later in the chapter. In the heart, aldosterone antagonists inhibit cardiac extracellular matrix and collagen deposition, thereby attenuating cardiac fibrosis and ventricular remodeling.[92] Spironolactone also interacts with androgen and progesterone receptors, which may lead to gynecomastia

and other sexual side effects in some patients. Such adverse effects are less frequent with eplerenone owing to its low affinity for the progesterone and androgen receptors.

Evidence that ACE inhibitors incompletely suppress aldosterone provided the impetus for examining the benefits of adding an aldosterone antagonist to ACE inhibitor therapy.[93] The Randomized Aldactone Evaluation Study (RALES) randomized over 1,600 patients with current or recent NYHA class IV heart failure to aldosterone blockade with spironolactone 25 mg daily or placebo.[22] Patients were also treated with standard therapy, usually including an ACE inhibitor, loop diuretic, and digoxin. Those with a serum creatinine concentration >2.5 mg/dL or a serum potassium concentration >5 mEq/L were excluded. The study was stopped prematurely after an average follow-up of 24 months because of a significant 30% reduction in the primary end point of total mortality with spironolactone. Spironolactone reduced mortality due to both progressive heart failure and sudden cardiac death. It also produced a 35% reduction in hospitalizations for worsening heart failure and significant symptomatic improvement, as assessed by changes in NYHA functional class. The low dose of spironolactone was well tolerated in RALES. The most common adverse effect was gynecomastia, which occurred in 10% of men on spironolactone compared with 1% of men on placebo, and led to treatment discontinuation in 2% of patients. There were statistically (but not clinically) significant increases in serum creatinine (by 0.05–0.10 mg/dL) and potassium concentrations (by 0.30 mEq/L) with spironolactone. The incidence of serious hyperkalemia (>6 mEq/L) was minimal and did not differ between spironolactone- and placebo-treated groups.

More recently, the EPHESUS trial evaluated the effect of selective antagonism of the mineralocorticoid receptor with eplerenone in patients with left ventricular dysfunction after MI.[23] To be eligible for study participation, patients had to have evidence of either heart failure or diabetes. Over 6,600 patients were randomized within 3 to 14 days of MI to eplerenone, titrated to 50 mg daily, or placebo in addition to standard therapy, which usually included an ACE inhibitor, β-blocker, aspirin, and diuretics. Similar to the RALES trial, patients with serum creatinine concentrations greater than 2.5 mg/dL or serum potassium concentrations greater than 5 mEq/L were excluded. Treatment with eplerenone was associated with a significant 15% relative reduction in the risk for death from any cause and a 15% reduction in the risk of hospitalization from heart failure. Serious hyperkalemia occurred in 5.5% of eplerenone-treated patients and 3.9% of placebo-treated patients. Eplerenone was not associated with gynecomastia.

The benefits of aldosterone antagonists in heart failure are not just due to the inhibition of aldosterone's actions in the heart resulting in inhibition of aldosterone-mediated cardiac fibrosis and ventricular remodeling. Recent evidence points to an important role of aldosterone antagonists in attenuating the systemic proinflammatory state and oxidative stress caused by aldosterone.[94,95] In addition, there is evidence that aldosterone antagonists may attenuate aldosterone-induced calcium excretion and reductions in bone mineral density and protect against fractures in heart failure.[96,97] And although spironolactone historically has been viewed as a diuretic, this is believed to contribute little to its benefits in heart failure, in part because the doses used have minimal diuretic effect.[22] Thus, as with ACE inhibitors and β-blockers, the data on aldosterone antagonists also support the neurohormonal model of heart failure.

Current guidelines recommend adding a low-dose aldosterone antagonist to standard therapy in select patients provided that potassium and renal function can be carefully monitored.[1] Based on data from RALES and EPHESUS, low-dose aldosterone antagonists are appropriate for two groups of patients: those with moderately severe to severe heart failure and reduced LVEF who are receiving standard therapy and those with left ventricular dysfunction early after MI.[1] For patients who fall outside the populations studied in these clinical trials, there are no clear guidelines on aldosterone antagonist use. Trials to address the efficacy of aldosterone antagonism in patients with mild to moderate heart failure symptoms and in patients with preserved left ventricular systolic function are ongoing. In the interim, guidelines state that it might be reasonable to consider use of aldosterone antagonists for some patients with mild to moderate symptoms. Such patients might include those who require potassium supplementation. The premise for use in this setting would be that it might be possible to reduce or eliminate potassium supplementation while potentially providing additional benefit with respect to altering the disease course.

Despite the clear benefits of aldosterone antagonists in patients with moderately severe to severe heart failure and left ventricular systolic dysfunction, registry data show that only one third of patients meeting guideline criteria for an aldosterone antagonist actually receive one.[98,99] The low use of aldosterone antagonists is likely due in large part to safety concerns. The clinical trial data suggest that aldosterone antagonists in heart failure are associated with minimal risk when used appropriately (e.g., in those with adequate renal function and with close laboratory monitoring). However, shortly after publication of RALES, an observational study of approximately 1.3 million elderly patients in the Ontario Drug Benefit Program found that the increase in the spironolactone prescription rate following the publication of RALES was accompanied by nearly threefold increases in the rate of hospital admissions and the rate of death related to hyperkalemia.[100] In addition, small case series showed that 25% to 35% of patients treated outside the controlled clinical trial setting developed hyperkalemia (>5 mEq/L) and that 10% to 12% developed serious hyperkalemia.[101,102]

Potential factors contributing to the high incidence of hyperkalemia in clinical practice include the initiation of aldosterone antagonists in patients with impaired renal function or high potassium concentrations and the failure to decrease or stop potassium supplements when starting aldosterone antagonists. Other risk factors for hyperkalemia include diabetes, inadequate laboratory monitoring, and concomitant use of both ACE inhibitors and ARBs or NSAIDs. ACC/AHA recently recommended strategies to minimize the risk for hyperkalemia with aldosterone antagonists in heart failure.[1] These strategies are summarized in Table 20–7. Chief among these recommendations is to avoid aldosterone antagonists in patients with renal dysfunction or elevated serum potassium. It is important to emphasize here that serum creatinine may overestimate renal function in the elderly and in patients with decreased muscle mass, in whom creatinine clearance should serve as a guide for the appropriateness of aldosterone antagonist therapy. The risk for hyperkalemia is dose dependent, and the morbidity and mortality reductions with aldosterone antagonists in clinical trials occurred at low doses (i.e., spironolactone 25 mg/day and eplerenone 50 mg/day). Therefore, the doses of aldosterone antagonists should be limited to those associated with beneficial effects in order to decrease the risk for hyperkalemia.

Only 10% of RALES participants were taking β-blockers at baseline because the benefits of β-blockers in heart failure were not appreciated fully at the time the trial began.[22] Beta-blockers inhibit plasma renin release and may provide additional suppression of the RAAS when used with ACE inhibitors. Thus, there has been some speculation about whether spironolactone will provide further benefit in patients receiving both ACE inhibitors and β-blockers. However, data from EPHESUS provide some clarity to this issue, as the majority of EPHESUS participants were on β-blockers at baseline, and the trial still demonstrated significant reductions in mortality with the addition of eplerenone.[23]

TABLE 20-7 Recommended Strategies for Reducing the Risk of Hyperkalemia with Aldosterone Antagonists

1. Avoid starting aldosterone antagonists in patients with any of the following:
   - Serum creatinine concentration >2 mg/dL in women or >2.5 mg/dL in men or a creatinine clearance <30 mL/min
   - Recent worsening of renal function
   - Serum potassium concentration ≥5 mEq/L
   - History of severe hyperkalemia
2. Start with low doses (12.5 mg/d for spironolactone and 25 mg/d for eplerenone), especially in the elderly and in those with diabetes or a creatinine clearance <50 mL/min.
3. Decrease or discontinue potassium supplements when starting an aldosterone antagonist.
4. Avoid concomitant use of NSAIDs or COX-2 inhibitors.
5. Avoid concomitant use of high-dose ACE inhibitors or ARBs.
6. Avoid triple therapy with an ACE inhibitor, ARB, and aldosterone antagonist.
7. Monitor serum potassium concentrations and renal function within 3 days and 1 week after the initiation or dose titration of an aldosterone antagonist or any other medication that could affect potassium homeostasis. Thereafter, potassium concentrations and renal function should be monitored monthly for the first 3 months, then every 3 months.
8. If potassium exceeds 5.5 mg/dL* at any point during therapy, discontinue any potassium supplementation, or, in the absence of potassium supplements, reduce or stop aldosterone antagonist therapy.
9. Counsel patients to
   - Limit intake of high potassium-containing foods and salt substitutes.
   - Avoid the use of nonprescription NSAIDs.
   - Temporarily discontinue aldosterone antagonist therapy if diarrhea develops or diuretic therapy is interrupted.

Abbreviations: ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; COX-2, cyclooxygenase-2; NSAID, nonsteroidal antiinflammatory drug.

Circulation 2009;119:e391–e479.

Digoxin 8 In 1785, William Withering was the first to report extensively on the use of foxglove or *Digitalis purpurea* for the treatment of dropsy (i.e., edema). Although digitalis glycosides have been in clinical use for more than 200 years, not until the 1920s were they clearly demonstrated to have a positive inotropic effect on the heart. Furthermore, it was not until the late 1980s that clinical trials were conducted to critically evaluate the role of digoxin in the therapy of systolic heart failure. The results of the Digitalis Investigation Group (DIG) trial helped clarify the role of digoxin in this setting.[103] The view of digoxin has also shifted over the past decade. Although it was historically considered useful in heart failure because of its positive inotropic effects, it now seems clear that its real benefits in heart failure are related to its neurohormonal modulating activity.[104,105]

The efficacy of digoxin in patients with heart failure and supraventricular tachyarrhythmias such as atrial fibrillation is well established and widely accepted. Its role in patients with normal sinus rhythm has been considerably more controversial. Until the 1980s, most data supporting the efficacy of digoxin in these patients came from anecdotal evidence and seriously flawed or uncontrolled studies. Since then, a number of clinical trials have shown that digoxin improves cardiac function, quality of life, exercise tolerance, and heart failure symptoms.[105,106] However, these studies involved small numbers of patients followed for short time periods. Although these trials demonstrated hemodynamic and symptomatic improvement in patients with heart failure receiving digoxin, an unresolved issue was the unknown effect of digoxin on mortality. This was of particular concern, given the increased mortality seen with other positive inotropic drugs, and finally led to organization and performance of the DIG trial to determine the effects of digoxin on survival in patients with heart failure in sinus rhythm.[103]

The DIG trial was a double-blind, randomized, placebo-controlled trial with the primary end point of all-cause mortality.[103] Patients (n = 6,800) with heart failure symptoms and an EF ≤45% were eligible for the main DIG trial and were randomized to received digoxin or placebo for a mean follow-up period of 37 months. Most patients received background therapy with diuretics and ACE inhibitors. Digoxin serum concentrations of 0.5 to 2 ng/mL were targeted, with a mean serum digoxin concentration of 0.8 ng/mL achieved after 12 months of therapy. No significant differences in all-cause mortality were found between patients receiving digoxin and placebo. A trend toward lower mortality due to worsening heart failure was observed in the digoxin group, although this was offset by a trend toward an increased mortality from other cardiovascular causes (presumably arrhythmias) in patients receiving digoxin. Importantly, digoxin reduced hospitalizations for worsening heart failure by 28% compared with placebo (P <0.001). Therefore, DIG is the first trial to show that a positive inotropic agent does not increase mortality and actually decreases morbidity in patients with heart failure and reduced systolic function. On the other hand, among an additional 988 patients with an EF greater than 45% (diastolic dysfunction) who were enrolled in an ancillary DIG trial, there was no apparent benefit of digoxin on hospitalizations or mortality during the 37-month follow-up period.[107]

The Prospective Randomized Study of Ventricular Failure and the Efficacy of Digoxin (PROVED) and Randomized Assessment of Digoxin and Inhibitors of Angiotensin-Converting Enzyme (RADIANCE) trials investigated the effect of digoxin withdrawal in patients with systolic heart failure and normal sinus rhythm and further defined the role of digoxin in this setting.[108,109] Both of these trials were short-term (12-week), prospective, randomized, and placebo-controlled and were conducted prior to the use of β-blockers. Together, data from these trials suggested that digoxin produces important symptomatic benefits and that digoxin withdrawal results in worsening heart failure, decreased exercise capacity, and a reduction in EF. A post hoc analysis of the DIG trial data supports previous findings that discontinuation of digoxin may be detrimental. Specifically, among patients treated with digoxin prior to enrollment in the DIG trial, those assigned to the placebo arm (i.e., those discontinuing digoxin therapy) had an increased risk of all-cause hospitalization and heart failure—related hospitalization compared with patients assigned to the digoxin arm (i.e., those continuing digoxin therapy).[110]

Retrospective analyses of the combined PROVED/RADIANCE database[111] and the DIG trial database[112] suggest that the clinical benefits of digoxin are achieved at lower serum digoxin concentrations (SDCs), with no additional benefit with higher concentrations. In particular, analysis of digoxin-treated patients in the PROVED and RADIANCE trials showed similar clinical outcomes among those with an SDC between 0.5 and 0.9 ng/mL as those with higher serum concentrations.[111] Although the DIG trial showed no reduction in mortality in the study population overall, a comprehensive analysis of the DIG trial database found that lower SDCs were associated with decreased mortality, whereas higher concentrations were not.[112] Specifically, compared with placebo, SDCs of 0.5 to 0.9 ng/mL 1 month after digoxin initiation were associated with lower mortality, all-cause hospitalizations, and heart failure hospitalizations. Serum concentrations greater than or equal 1 ng/mL were associated with lower heart failure hospitalizations with no effect on mortality. A digoxin dose of ≤0.125 mg daily was predictive of SDCs of 0.4 to 0.9 ng/mL. Although an initial, well-publicized study suggested that digoxin might be harmful in women,[113] subsequent analyses show no increased risks with digoxin in women, particularly with SDCs less than 1 ng/mL.[112,114]

Another post hoc analysis of DIG trial data evaluated the effect of digoxin on mortality at 1 year.[115] In contrast to the original DIG

data, the investigators observed a reduction in all-cause mortality in addition to reductions in heart failure—related mortality and all-cause hospitalizations with digoxin compared with placebo. The investigators postulated that increased use of open-label digoxin in the placebo group and worsening renal function over time leading to increased SDCs in the digoxin group may explain the lack of sustained effects of digoxin on mortality. Because this analysis was retrospective and nonprespecified, the results should be interpreted with caution. However, it provides reassurance of the safety of digoxin early after initiation.

Based on the available data, for most patients, the target SDC should be 0.5 to 1 ng/mL. This more conservative target would also be expected to decrease the risk of adverse effects from digoxin toxicity. In fact, recent assessment of the rate of digoxin toxicity has suggested a significant decline in the overall incidence.[116] In most patients with normal renal function, this serum concentration range can be achieved with a daily dose of 0.125 mg. Patients with decreased renal function, the elderly, or those receiving interacting drugs (e.g., amiodarone) should receive 0.125 mg daily or every other day. Routine measuring of SDCs is not necessary in the absence of suspected digoxin toxicity, worsening renal function, institution of an interacting drug, or other conditions that may significantly affect SDC. In patients with atrial fibrillation and a rapid ventricular response, the historic practice of increasing digoxin doses (and concentrations) until rate control is achieved is no longer recommended. Digoxin alone is often ineffective in controlling ventricular response in patients with atrial fibrillation, and increasing the dose only increases the risk of toxicity. Digoxin combined with a β-blocker or amiodarone is superior to either agent alone for controlling ventricular response in patients with atrial fibrillation and heart failure.[1] Therefore, target SDCs are the same regardless of whether the patient is in sinus rhythm or atrial fibrillation. Several equations and nomograms have been proposed to estimate digoxin maintenance doses based on estimated renal function for a particular patient and population pharmacokinetic parameters. These methods are extensively reviewed elsewhere.[117] More recently, based on post hoc analyses from the DIG, PROVED, and RADIANCE trials, investigators developed a digoxin-dosing nomogram that targets a lower digoxin plasma concentration.[118] In the absence of supraventricular tachyarrhythmias, a loading dose is not indicated because digoxin is a mild inotropic agent that will produce gradual effects over several hours, even after loading.

Digoxin's place in the pharmacotherapy of systolic heart failure can therefore be summarized for two patient groups. In patients with heart failure and supraventricular tachyarrhythmias such as atrial fibrillation, it should be considered early in therapy to help control the ventricular response rate. For patients in normal sinus rhythm, although digoxin does not improve survival, its effects on symptom reduction and clinical outcomes are evident in patients with mild to severe heart failure with reduced systolic function. Thus, it should be used in conjunction with other standard heart failure therapies, including diuretics, ACE inhibitors, and β-blockers, in patients with symptomatic heart failure to reduce hospitalizations. In the absence of digoxin toxicity or serious adverse effects, digoxin should be continued in most patients. Digoxin withdrawal may be considered for asymptomatic patients who have significant improvement in systolic function with optimal ACE inhibitor and β-blocker treatment.[106]

Nitrates and Hydralazine ⑩ Nitrates and hydralazine were combined originally in the treatment of heart failure because of their complementary hemodynamic actions. Nitrates, by serving as nitric oxide donors, activate guanylate cyclase to increase cyclic guanosine monophosphate (cGMP) in vascular smooth muscle. This results in venodilation and reductions in preload. Hydralazine is a direct-acting vasodilator that acts predominantly on arterial smooth muscle to reduce SVR and increase stroke volume and cardiac output (see Fig. 20–1). Hydralazine also has antioxidant properties and appears to prevent nitrate tolerance.[119] Evidence also suggests that the combination of hydralazine and nitrates may exert beneficial effects beyond their hemodynamic actions by interfering with the biochemical processes associated with heart failure progression.[1,120]

The efficacy of the combination of hydralazine and isosorbide dinitrate (ISDN) has been evaluated in three large, randomized heart failure trials. The first trial predated the use of ACE inhibitors and β-blockers in heart failure and found that the combination of hydralazine 75 mg and ISDN 40 mg, each given four times daily, reduced mortality compared with placebo in patients receiving diuretics and digoxin.[121] However, a subsequent trial comparing the combination with an ACE inhibitor demonstrated greater mortality reduction with the ACE inhibitor.[122] Post hoc analysis of these trials suggested that the combination of hydralazine and ISDN was particularly effective in African Americans and led to examining the efficacy of adding the combination to standard therapy in this group.[123]

The African-American Heart Failure Trial (A-HeFT) randomized 1,050 self-identified African Americans with NYHA class III or IV heart failure to hydralazine plus ISDN or placebo, each in addition to standard therapy, usually including an ACE inhibitor (or ARB), β-blocker, and diuretic, with or without digoxin and spironolactone.[120] The trial used a fixed-dose combination product, BiDil, that contains hydralazine 37.5 mg and ISDN 20 mg. Therapy was initiated as a single tablet given three times daily, then titrated to two tablets three times daily if tolerated. The trial was terminated early after a mean follow-up of 10 months because of a significant 43% reduction in all-cause mortality in patients receiving hydralazine/ISDN compared with placebo. The primary composite end point of mortality, hospitalizations for heart failure, and quality of life was also significantly improved with the combination product. Based on these results, BiDil was approved by the FDA to treat heart failure exclusively in African Americans.

The mechanism for the beneficial effects of hydralazine/ISDN is believed to relate to an increase in nitric oxide bioavailability secondary to nitric oxide donation from ISDN and a hydralazine-mediated reduction in oxidative stress.[119] Nitric oxide has been shown to attenuate myocardial remodeling and may play a protective role in heart failure. It is suggested that African Americans have less nitric oxide availability compared with non—African Americans, and thus may derive particular benefit from therapy that enhances nitric oxide bioavailability. Whether the benefits of adding hydralazine/ISDN to standard therapy extend to non—African Americans remains to be prospectively evaluated. However, a recent nonrandomized trial found that the addition of ISDN and hydralazine improved hemodynamics and clinical outcomes (all-cause mortality and the combined end point of mortality and heart failure hospitalization) in patients of any race with advanced systolic heart failure receiving ACE inhibitors and/or ARBs who were discharged from the hospital after an episode of acute decompensated heart failure.[124]

Approximately 350 A-HeFT participants were enrolled in a genetic substudy to examine whether genotype influenced response to hydralazine/ISDN. Separate analyses examined the associations between the endothelial nitric oxide synthase-3 (*NOS3*) Glu298Asp and corin Gln568Pro variants and treatment outcomes.[125,126] The *NOS3* study showed that hydralazine/ISDN improved the composite end point of survival, hospitalization, and quality of life in those with the Glu/Glu genotype, but not in those with the Asp allele.[125] The corin study suggested that hydralazine/ISDN abolishes adverse consequences of the 568Pro allele. Corin is a protein expressed in cardiomyocytes that cleaves pro-ANP and pro-BNP into active natriuretic peptides. The corin 568Pro variant leads to a dysfunctional protein and lower BNP levels.[126] Among A-HeFT

participants in the placebo group, the 568Pro allele was associated with an increased risk for death or heart failure hospitalization.[126] However, no detrimental effect of the 568Pro variant was observed in the hydralazine/ISDN treatment group. Both the *NOS3* Glu/Glu genotype and corin 568Pro variant occur predominantly in persons of African descent, potentially explaining why hydralazine/ISDN is especially effective in African Americans.

In the future, treatment with hydralazine and nitrates could be guided by genotype. Until then, current guidelines recommend the addition of hydralazine and nitrates to self-described African Americans with moderate to severe symptoms despite therapy with ACE inhibitors, diuretics, and β-blockers.[1] This combination is also reasonable to consider in all patients who continue to have symptoms despite optimized therapy with an ACE inhibitor (or ARB) and β-blocker.[1] For patients unable to tolerate an ACE inhibitor because of cough or angioedema, an ARB is recommended as the first-line alternative.[1] Hydralazine and a nitrate might be reasonable in patients unable to tolerate either an ACE inhibitor or an ARB because of renal insufficiency, hyperkalemia, or possibly hypotension.[1]

There are several potential obstacles to successful therapy with hydralazine and nitrates in heart failure. The first is the need for frequent dosing, with the fixed-dose combination dosed three times daily and the individual drugs dosed four times daily in clinical trials. Second, adverse effects are common with hydralazine/nitrates, with headache, dizziness, and GI distress occurring more frequently with hydralazine/nitrates compared with placebo in clinical trials.[120,121] A third potential obstacle is the high cost of the brand-name fixed-dose combination product compared with the individual generic drugs purchased separately. Because of the high cost of the combination product, many clinicians use generic hydralazine and isosorbide as separate agents rather than the combination product, although this approach has not been evaluated in clinical trials.

Treatment of Concomitant Disorders

Heart failure is often accompanied by other disorders whose natural history or therapy may affect morbidity and mortality. In select patients, optimal management of these concomitant disorders may have a profound impact on heart failure symptoms and outcomes.

Hypertension Although ischemic heart disease has replaced hypertension as the most common cause of heart failure, still nearly two thirds of heart failure patients have current hypertension or a previous history of hypertension.[1] Hypertension can contribute directly to the development of left ventricular systolic and/or diastolic dysfunction and heart failure. It can also contribute indirectly by increasing the risk of coronary artery disease. Effective treatment of hypertension reduces the risk of developing heart failure, especially in patients with diabetes.[1]

Pharmacotherapy of hypertension in patients with heart failure should initially involve agents that can treat both disorders, such as ACE inhibitors, β-blockers, and diuretics. Target levels of blood pressure should be consistent with current guidelines.[1,46] If control of hypertension is not achieved after optimizing treatment with these agents, the addition of an ARB, aldosterone antagonist, isosorbide dinitrate/hydralazine, or a second-generation calcium channel blocker such as amlodipine (or possibly felodipine) should be considered. Medications that should be avoided include the calcium channel blockers with negative inotropic effects (e.g., verapamil, diltiazem, and most dihydropyridines) and direct-acting vasodilators (e.g., minoxidil) that cause sodium retention.

Angina Coronary artery disease is the most common heart failure etiology. Appropriate management of coronary disease and its risk factors is thus an important strategy for the prevention and treatment of heart failure. Coronary revascularization should be strongly considered in patients with both heart failure and angina.[1] Pharmacotherapy of angina in patients with heart failure should utilize drugs that can successfully treat both disorders. Nitrates and β-blockers are effective antianginals and are the preferred agents for patients with both disorders, as they may improve hemodynamics and clinical outcomes.[1] It should be noted that the antianginal effectiveness of these agents may be significantly limited if fluid retention is not controlled with diuretics. Similar to their use in hypertension, both amlodipine and felodipine appear to be safe to use in this setting. Optimization of other treatments for secondary prevention of coronary and other atherosclerotic vascular disease should also be considered.[46] Two large trials found that despite significant reductions in low-density lipoprotein (LDL) cholesterol, rosuvastatin did not improve outcomes including mortality, nonfatal MI, nonfatal stroke, or hospital admission for cardiovascular causes in patients with heart failure and reduced LVEF.[31,32] Therefore, the current data do not support the routine use of statins in systolic heart failure, although the precise role of statins in these patients remains controversial.

Atrial Fibrillation Atrial fibrillation is the most frequently encountered arrhythmia. It is commonly found in patients with heart failure, affecting 10% to 50% of patients, with the prevalence increasing in parallel to the severity of heart failure.[35] The high incidence of atrial fibrillation in the heart failure population is not surprising, as each of these two disorders predisposes to the other, and they share many risk factors, including coronary artery disease, diabetes, obesity, and hypertension. The presence of atrial fibrillation in patients with heart failure is associated with a worse long-term prognosis.[1,35] The combination of atrial fibrillation and heart failure may exert a number of detrimental effects, which include increased risk of thromboembolism secondary to stasis of blood in the atria, a reduction in cardiac output due to loss of the atrial contribution to ventricular filling, and hemodynamic compromise from the rapid ventricular response.[35] Moreover, heart failure exacerbations and atrial fibrillation are closely linked, and it is often difficult to determine which disorder caused the other. For example, worsening heart failure results in volume overload, which in turn causes atrial distention and increases the risk of atrial fibrillation. Similarly, atrial fibrillation with a rapid ventricular response can reduce cardiac output and lead to heart failure exacerbation. Thus, optimal management according to established guidelines is required, with careful attention paid to control of ventricular response and anticoagulation for stroke prevention (see Chapter 25).[127]

Recent studies suggest that ACE inhibitors, ARBs, and β-blockers decrease the incidence of atrial fibrillation in patients with heart failure, providing further support for their use in these patients.[128,129] Digoxin is frequently used to slow ventricular response in patients with heart failure and atrial fibrillation. However, it is more effective at rest than with exercise, and it does not affect the progression of heart failure. Beta-blockers are more effective than digoxin and have the added benefits of improving heart failure—related morbidity and mortality. Combination therapy with digoxin and a β-blocker may be more effective for rate control than either agent used alone. Calcium channel blockers with negative inotropic effects such as verapamil and diltiazem should be avoided. Amiodarone is a reasonable alternative for rate control in those patients not responding to digoxin and/or β-blockers or with contraindications to these agents.[127] Appropriate selection of antithrombotic therapy for stroke prevention that takes into consideration the presence of risk factors for thromboembolism in an individual patient is also required.[127]

Because of the close association between atrial fibrillation, heart failure exacerbations, and hospitalizations, restoration and maintenance of sinus rhythm (i.e., rhythm control) is often attempted instead of the rate control approach. Although initial trials such as

AFFIRM showed no difference in outcomes between the rhythm control and rate control approaches, less than 10% of the patients in this study had significant left ventricular dysfunction.[130] The Atrial Fibrillation and Congestive Heart Failure (AF-CHF) trial prospectively compared the rhythm and rate control approaches in nearly 1,400 patients with symptomatic heart failure and LVEF ≤35%.[131] Rhythm control was primarily achieved with amiodarone, whereas a β-blocker and digoxin were used for rate control. Compared with rate control, there were no improvements in mortality, stroke, death from cardiovascular causes, or heart failure hospitalizations in the rhythm control arm. Therefore, overall rhythm control appears to offer no specific advantages over rate control in this population and can be reserved for patients in whom the rate cannot be controlled or who remain symptomatic. In general, amiodarone is the preferred agent if the rhythm control approach is taken. Although it has many noncardiac toxicities, amiodarone does not have cardiodepressant or significant proarrhythmic effects and appears to be safe in heart failure. Dofetilide also appears to be safe and effective in this population.[35,127] Class I antiarrhythmics should be avoided.[35,127]

Diabetes Diabetes is highly prevalent in the heart failure population, with current estimates indicating it is present in approximately one third of patients with heart failure.[38,132] As an important risk factor for coronary artery disease, diabetes directly contributes to the development of heart failure. Importantly, though, diabetes is a risk factor for heart failure independent of coronary artery disease or hypertension, is associated with hastened heart failure progression, and is a significant predictor of mortality in patients with heart failure.[132]

Pharmacotherapy of diabetes in patient with heart failure is complicated by concerns about adverse effects associated with metformin and the thiazolidinedione (TZD) drugs (rosiglitazone and pioglitazone). The beneficial effects of these agents on glucose control and cardiovascular risk factors lead to their widespread use in patients with heart failure despite the warnings in the product labeling against their use.[132] Use of metformin in patients with heart failure has been contraindicated because of the purported risk of lactic acidosis. However, the product labeling was recently revised removing this contraindication, although a warning still remains specifically in patients with hypoperfusion and hypoxemia. Data from observational studies and a systematic review suggest that metformin is safe (no reports of lactic acidosis or hospital admissions) and is associated with decreased mortality in patients with heart failure.[133,134] Therefore, some clinicians suggest that the concerns about metformin use in hemodynamically stable patients with normal renal function should be reexamined. However, the lack of prospective data about the safety and efficacy of metformin in this population suggests that if metformin is used, it should be used cautiously with careful monitoring of volume status and renal function.[132]

Although the mechanisms are presently unclear, TZDs are associated with weight gain, peripheral edema, and heart failure. The TZD package inserts indicate these agents should not be used in patients with NYHA class III or IV heart failure because they may cause intravascular volume expansion and heart failure exacerbation. Most clinical trials with these drugs excluded patients with moderate to severe heart failure; thus, there is a lack of prospective data to guide clinical decision making. A systematic review and an observational study both suggest TZDs do not increase mortality but do increase the risk of hospital admission for heart failure.[133,134] Because of the potential risk, a recent consensus statement indicates TZDs should not be used in patients with NYHA class III or IV heart failure.[38] TZDs should be used cautiously in patients with class I or II symptoms, with close observation needed to detect weight gain, edema formation, or heart failure exacerbation.[38]

Anemia Anemia occurs frequently in patients with heart failure and is associated with worse clinical outcomes, including increased risk of death, hospitalization for heart failure, reduced exercise capacity, and worse quality of life.[135] The exact cause of anemia in patients with heart failure is uncertain but likely involves reduced response to erythropoietin, the presence of inhibitors to hematopoiesis, renal dysfunction, proinflammatory state, bone marrow suppression, and/or iron deficiency.[135] As a result, there is widespread interest in the correction of anemia as a therapeutic target in heart failure. A recent meta-analyis suggests erythropoiesis-stimulating agents improve symptoms and exercise capacity and decrease plasma natriuretic peptide levels in patients with heart failure and anemia.[136] A recently completed trial using darbepoetin in patients with type 2 diabetes, chronic kidney disease, and anemia (~30% of the patients had heart failure) did not improve cardiovascular outcomes and increased the risk of stroke.[137] Administration of IV iron to patients with NYHA class II or III symptoms, an LVEF ≤45%, and iron deficiency was associated with improvements in exercise capacity and quality of life with no increased risk of adverse events.[138] The results of ongoing prospective trials are needed to characterize the risks and benefits of treating anemia in this population.

Drug Class Information

Diuretics 7 Loop diuretics, as described earlier, represent the typical diuretic therapy for patients with heart failure due to their potency and, as such, are the only diuretics discussed here.[57] There are currently three loop diuretics available that are used routinely: furosemide, bumetanide, and torsemide. They share many similarities in their pharmacodynamics, with their differences being largely pharmacokinetic in nature. Relevant information on the loop diuretics is shown in Table 20–5. Following oral administration, the peak effect with all the agents occurs in 30 to 90 minutes, with duration of 2 to 3 hours (slightly longer for torsemide). Following IV administration, the diuretic effect begins within minutes. All three drugs are highly (>95%) bound to serum albumin and enter the nephron by active secretion in the proximal tubule. The magnitude of effect is determined by the peak concentration achieved in the nephron, and there is a threshold concentration that must be achieved before any diuresis is seen.

The biggest difference between the agents is bioavailability. Bioavailability of bumetanide and torsemide is essentially complete (80–100%), whereas furosemide bioavailability exhibits marked intra- and interpatient variability. Furosemide bioavailability ranges from 10% to 100%, with an average of 50%. Thus, if bioequivalent IV and oral doses are desired, oral furosemide doses should be approximately double that of the IV dose, whereas IV and oral doses are the same for torsemide and bumetanide. Coadministration of furosemide and bumetanide with food can decrease bioavailability significantly, whereas food has no effect on the bioavailability of torsemide. The intra-abdominal congestion that can occur in heart failure also may slow the rate (and thus decrease the peak concentration) of furosemide, which can reduce the diuretic's efficacy. Thus, furosemide is most problematic with respect to rate and extent of absorption and the factors that influence it, whereas torsemide has the least variable bioavailability.

Recent data suggest that these differences in bioavailability and variability may have clinical implications. For example, several studies have suggested that torsemide is absorbed reliably and is associated with better outcomes than the more variably absorbed furosemide.[139,140] Torsemide is preferred in patients with persistent fluid retention despite high doses of other loop diuretics. Although the costs of torsemide exceed those of furosemide, pharmacoeconomic analyses suggest that the costs of care are similar or less with torsemide.[140] These data require confirmation in double-blind,

controlled clinical trials but provide preliminary evidence that the more reliably absorbed loop diuretics may be superior to furosemide.

The loop diuretics exhibit a ceiling effect in heart failure, meaning that once the ceiling dose is reached, no additional response is achieved by increasing the dose. Thus, when this dose is reached, additional diuresis is achieved by giving the drug more often (twice daily or occasionally three times daily) or by giving combination diuretic therapy. The ceiling doses are listed in Table 20–5. Multiple daily dosing achieves a more sustained diuresis throughout the day. When dosed two or three times daily, the first dose is usually given first thing in the morning and the final dose in late afternoon/early evening.

Diuretics cause a variety of metabolic abnormalities, with severity related to the potency of the diuretic. The reader is referred to Chapter 19 for a detailed discussion of the adverse effects of diuretic therapy. Hypokalemia is the most common metabolic disturbances with thiazide and loop diuretics, which in patients with heart failure may be exacerbated by hyperaldosteronism. Hypokalemia increases the risk for ventricular arrhythmias in heart failure and is especially worrisome in patients receiving digoxin. Hypokalemia is often accompanied by hypomagnesemia. Because adequate magnesium is necessary for entry of potassium into the cell, cosupplementation with both magnesium and potassium may be necessary to correct the hypokalemia. Concomitant ACE inhibitor (or ARB) and/or aldosterone antagonist therapy may help to minimize diuretic-induced hypokalemia because these drugs tend to increase serum potassium concentration through their inhibitory effect on aldosterone secretion. Nonetheless, the serum potassium concentration should be monitored closely in patients with heart failure and supplemented appropriately when needed. In addition to metabolic abnormalities, a recent post hoc analysis of the DIG trial suggested that chronic diuretic use was associated with increased risk of mortality and hospitalization.[141] These findings must be interpreted with caution because this trial was not designed to evaluate outcomes associated with diuretic therapy. However, they do serve to remind clinicians of the importance of appropriate patient selection and monitoring when using diuretic therapy.

ACE Inhibitors 5 A number of ACE inhibitors are currently available; those commonly used in the treatment of patients with heart failure are summarized in Table 20–8. Although ACE inhibitors vary in their chemical structure (e.g., sulfhydryl- vs nonsulfhydryl-containing agents) and tissue affinity, the major differences in the ACE inhibitors are not in these pharmacologic properties but in their pharmacokinetic properties.[17] To date all ACE inhibitors studied have shown improvement in heart failure symptoms or mortality.[17] However, it seems most prudent to use those agents documented to reduce morbidity and mortality because the dose required for these end points has been determined.[1]

To minimize the risk of hypotension and renal insufficiency, ACE inhibitor therapy should be started with low doses followed by gradual titration as tolerated to the target doses.[1] Asymptomatic hypotension should not be considered a contraindication to initiation of an ACE inhibitor, although initiation or dose increases in patients with systolic blood pressures less than 90 to 100 mm Hg should be done cautiously. Renal function and serum potassium should be evaluated within 1 to 2 weeks after therapy is started with subsequent periodic assessments, especially after dose increases. Careful attention to appropriate doses of diuretics is important, as fluid overload may blunt the beneficial effects of ACE inhibitors, and overdiuresis increases the risk of hypotension and renal insufficiency. After titration of the drug to the target dose, most patients tolerate chronic therapy with few complications. Although symptoms may improve within a few days of initiating therapy, it may take weeks to months before the full benefits are apparent. Even if symptoms do not improve, long-term ACE inhibitor therapy should be continued to reduce the risk of mortality and hospitalization.

Because ACE inhibitors were the first agents to show improvements in heart failure survival and were frequently used as background therapy in clinical trials of other medications, they are often used as the initial therapy in patients with heart failure. Traditionally, after titration of the ACE inhibitor dose, the addition of β-blockers was then considered. The expected ACE inhibitor—mediated decrease in blood pressure made some clinicians reluctant to initiate β-blocker therapy. Because of the impressive benefits of β-blockers, initiation of β-blocker therapy should not be delayed in patients who fail to reach target ACE inhibitor doses, as low-intermediate ACE inhibitor doses are as effective as higher doses for improving symptoms and survival.[1,65] Also, in β-blocker clinical trials, most patients were receiving background therapy with low-intermediate ACE inhibitor doses. Thus, in most patients, ACE inhibitors should be the initial therapy, but it is important to remember that the greatest benefit is seen when both an ACE inhibitor and a β-blocker are used.

Because of the high prevalence of coronary artery disease in patients with heart failure, aspirin is frequently coadministered with ACE inhibitors. Whether aspirin may attenuate the hemodynamic and mortality benefits of ACE inhibitors remains controversial.[142,143] The postulated mechanism of this interaction involves opposing effects on synthesis of vasodilatory prostaglandins. The ACE inhibitor—mediated increase in bradykinin increases the synthesis of vasodilatory prostaglandins that have favorable hemodynamic benefits in heart failure. Because of aspirin's effect on prostaglandin synthesis, this potentially beneficial action of ACE

TABLE 20-8 ACE Inhibitors Routinely Used for the Treatment of Heart Failure

Generic Name	Brand Name	Initial Dose	Target Dosing: Survival Benefit[a]	Elimination[b]
Captopril	Capoten	6.25 mg tid	50 mg tid	Renal
Enalapril	Vasotec	2.5–5 mg bid	10–20 mg bid	Renal
Lisinopril	Zestril, Prinivil	2.5–5 mg once daily	20–40 mg once daily[c]	Renal
Quinapril	Accupril	5 mg bid	20–40 mg bid[d]	Renal
Ramipril	Altace	1.25–2.5 mg bid	5 mg bid	Renal
Fosinopril	Monopril	5–10 mg once daily	40 mg once daily[d]	Renal/hepatic
Trandolapril	Mavik	0.5–1 mg once daily	4 mg once daily	Renal/hepatic
Perindopril	Aceon	2 mg once daily	8–16 mg once daily[d]	Renal/hepatic

Abbreviations: bid, twice daily; tid, three times daily.

[a]Target doses associated with survival benefits in clinical trials.

[b]Primary route of elimination.

[c]Note that in the ATLAS trial (Circulation 1999;100:2312–2318), no significant difference in mortality was found between low-dose (~5 mg/d) and high-dose (~35 mg/d) lisinopril therapy.

[d]Effects on mortality have not been evaluated.

inhibitors may be attenuated. However, in contrast with studies that showed an ACE inhibitor—aspirin interaction, other investigators have found no interaction, even in patients without coronary artery disease or with impaired renal function.[143,144] It is currently recommended that the decision to use each of these medications be made based on whether an individual patient has indications for each drug. Use of aspirin doses of 160 mg per day or less should be considered.

Adverse Effects The primary adverse effects of ACE inhibitors are secondary to their major pharmacologic effects of suppressing angiotensin II and increasing bradykinin. The reductions in angiotensin II are associated with hypotension and functional renal insufficiency, which are the most adverse effects observed with these agents. ACE inhibitors reduced blood pressure in nearly all patients with hypotension, becoming problematic when symptoms such as dizziness, lightheadedness, blurred vision, presyncope, and syncope are observed. Hypotension occurs most commonly early in therapy or after an increase in dose, although it may occur at any time during treatment. Risk factors for hypotension include hyponatremia (serum sodium <130 mEq/L), hypovolemia, and overdiuresis.[1] The occurrence of hypotension may be minimized by initiating therapy with lower ACE inhibitor doses and/or temporarily withholding or reducing the dose of diuretic and liberalizing salt and fluid intake.[1] An often overlooked solution to hypotension is to space the administration times of vasoactive medications (e.g., diuretics and β-blockers) throughout the day so that these medications are not all administered at or near the same time. Many patients who experience symptomatic hypotension early in therapy are still good candidates for long-term treatment if risk factors for low blood pressure are addressed.

Functional renal insufficiency is manifested as increases in serum creatinine and blood urea nitrogen (BUN). As cardiac output and renal blood flow decline, renal perfusion is maintained by the vasoconstrictor effect of angiotensin II on the efferent arteriole. Patients most dependent on this system for maintenance of renal perfusion (and therefore most likely to develop functional renal insufficiency with ACE inhibitors) are those with severe heart failure, hypotension, hyponatremia, volume depletion, bilateral renal artery stenosis, and concomitant use of NSAIDs.[145] Sodium depletion, usually secondary to diuretic therapy, is the most important factor in the development of functional renal insufficiency with ACE inhibitor therapy. Renal insufficiency therefore can be minimized in many cases by reduction of diuretic dosage or liberalization of sodium intake. Increases in serum creatinine of 10% to 20% from baseline are commonly observed after initiation of ACE inhibitor therapy. In some patients, the serum creatinine will return to baseline levels without a reduction in ACE inhibitor dose.[145] Increases in serum creatinine of >0.5 mg/dL if the baseline creatinine is <2 mg/dL or >1 mg/dL if the creatinine is >2 mg/dL should prompt clinicians to reconsider ACE therapy and evaluate potential causes for the abrupt decline in renal function.[145] The safety and efficacy of ACE inhibitors in patients with baseline serum creatinine >2.5 mg/dL are uncertain, as these patients were usually excluded from clinical trials. Caution should also be exercised when using ACE inhibitors in such patients. Because renal dysfunction with ACE inhibitors is secondary to alterations in renal hemodynamics, it is almost always reversible upon discontinuation of the drug.[145]

Careful dose titration can minimize the risks of hypotension and transient worsening of renal function. Thus, usual initial doses should be about one fourth the final target dose, with slow upward dose titration based on blood pressure and serum creatinine. In certain patients, especially those hospitalized patients who seem at high risk for hypotension or worsening of renal function, it may be advisable to initiate therapy with a short-acting agent such as captopril. This will help minimize the duration of adverse effects should they occur. Once stabilized on captopril, the patient can then be switched to an ACE inhibitor given once daily.

Retention of potassium with ACE inhibitor therapy can occur and is due to the reduced feedback of angiotensin II to stimulate aldosterone release. Hyperkalemia is most likely to occur in patients with renal insufficiency and in those taking concomitant potassium supplements, potassium-containing salt substitutes, or potassium-sparing diuretic therapy (including an aldosterone antagonist), especially if they have diabetes.[145] The more widespread use of aldosterone antagonists (e.g., spironolactone) in patients with heart failure may increase the risk of hyperkalemia.[100]

ACE inhibitors are associated with other important adverse effects. A dry, hacking cough occurs with a similar frequency (5–15% of patients) with all the agents and is related to bradykinin accumulation. The cough is usually nonproductive, occurs within the first few months of therapy, resolves within 1 to 2 weeks of drug discontinuation, and reappears with rechallenge. Cough occurs in up to 40% of patients with heart failure, independent of ACE inhibitor use; therefore, it is important to rule out other potential causes of cough, such as pulmonary congestion. Because cough is a bradykinin-mediated effect, replacement of ACE inhibitor therapy with an ARB would be reasonable in those patients who cannot tolerate the cough. Angioedema is a rare but potentially life-threatening complication that is also believed to be related to bradykinin accumulation. It may occur more frequently in African Americans than in other populations.[1] Use of ACE inhibitors is contraindicated in patients with a history of angioedema. ARBs may be an alternative therapy in patients with ACE inhibitor—induced angioedema, although caution is advised, as rare cross-reactivity is reported.[1,86,90] ACE inhibitors are contraindicated during the second and third trimesters of pregnancy due to the increased risk of fetal renal failure, intrauterine growth retardation, and other congenital defects. A recent analysis using a Medicaid database of nearly 30,000 patients suggests that first trimester use of ACE inhibitors should also be avoided, as the risk of major congenital defects was increased 2.7-fold in infants exposed to these agents during the first trimester.[146]

Angiotensin II Receptor Blockers 5 Although ACE inhibitors remain the agents of first choice to treat stage C heart failure with reduced LVEF, ARBs approved for the treatment of heart failure are now the recommended alternatives in patients who are unable to tolerate an ACE inhibitor.[1] Although numerous ARBs are currently available, only two, candesartan and valsartan, are approved for the treatment of heart failure. The efficacy of these two agents is supported by clinical trial data that document a target dose associated with improved survival and other important outcomes in patients with decreased LVEF.[82–84,86] Thus, candesartan and valsartan are the preferred agents in patients with heart failure, whether used alone or in combination with ACE inhibitors. ARBs are also alternatives to ACE inhibitors in patients with stage A or B heart failure.[1]

The clinical use of ARBs is similar to that of ACE inhibitors. Therapy should be initiated at low doses (candesartan 4–8 mg once daily, valsartan 20–40 mg twice daily) and then titrated to target doses (candesartan 32 mg once daily, valsartan 160 mg twice daily).[1] Blood pressure, renal function, and serum potassium should be evaluated within 1 to 2 weeks after initiation of therapy and after increases in dose, and these end points should be used to guide subsequent dose changes. It is not necessary to reach target doses before adding a β-blocker, although incremental benefits may be associated with higher doses of ARBs.[88]

Adverse Effects ARBs have a low incidence of adverse effects. Because they do not affect bradykinin, they are not associated with

cough and have a lower risk of angioedema than ACE inhibitors. However, because of reports of recurrences of ACE inhibitor—related angioedema after ARB administration, ARBs should be used cautiously in any patient with a history of angioedema, as a recent meta-analysis suggests that from 2% to 17% of patients experiencing angioedema with an ACE inhibitor will cross-react with an ARB.[86,90,147] The major adverse effects are related to suppression of the RAAS. The incidence and risk factors for developing hypotension, decreases in renal function, and hyperkalemia with the ARBs are similar to that of ACE inhibitors.[81] Thus, ARBs are not alternatives in patients who develop these complications from ACE inhibitors. Careful monitoring is required when an ARB is used with another inhibitor of the RAAS (e.g., ACE inhibitor or aldosterone antagonist), as this combination increases the risk of these adverse effects. As with ACE inhibitors, ARBs are contraindicated in the second and third trimesters of pregnancy and should be avoided in the first trimester because of increased risk of fetal/neonatal morbidity and mortality. Neither candesartan nor valsartan is metabolized by the cytochrome P450 system, so no pharmacokinetic drug—drug interactions with these agents are expected.

β-Blockers 6 Metoprolol CR/XL, carvedilol, and bisoprolol are the only β-blockers shown to reduce mortality in large heart failure trials. Metoprolol and bisoprolol selectively block the β_1-receptor, whereas carvedilol blocks the β_1-, β_2-,and α_1-receptors and also possesses antioxidant effects. Although there is no clear evidence that these pharmacologic differences result in differences in efficacy among agents, they may aid in selection of a specific agent. For example, carvedilol is expected to have greater antihypertensive effects than the other agents because of its α-receptor-blocking properties and may be preferred in patients with poorly controlled blood pressure. Conversely, metoprolol or bisoprolol may be preferred in patients with low blood pressure or dizziness and in patients with significant airway disease.

Bisoprolol is eliminated approximately 50% by the kidneys, whereas metoprolol and carvedilol are essentially completely metabolized and undergo extensive hepatic first-pass metabolism. Both metoprolol and carvedilol are also substrates for the cytochrome P450 2D6, which is known to be polymorphic. The 7% of the white population and 1% to 2% of the Asian American and African American populations who are CYP2D6 poor metabolizers would be expected to have more pronounced plasma concentrations than anticipated at the usual doses of carvedilol and metoprolol. However, given that β-blockers have a wide therapeutic index, it is unclear whether CYP2D6 phenotype significantly impacts hemodynamic and clinical effects.

There is fairly strong evidence that benefits of β-blockers in heart failure are not a class effect. Specifically, in a study powered for mortality reduction, there was no difference in survival between the nonselective β-blocker bucindolol and placebo.[148] Although there has been considerable debate over why bucindolol failed to provide a survival benefit, it may be related to the drug's ancillary properties or differences among β-blocker trials in the characteristics of study participants. Additional data suggest that bucindolol's effects on survival might be genotype specific, with a potential survival benefit in patients with the β_1-adrenergic receptor Arg389Arg genotype, but not in those with the Gly389 allele.[149] However, in the absence of bucindolol approval for heart failure, β-blocker use should be confined to one of the agents with proven survival benefits, especially given the diversity among β-blockers in their receptor sensitivities and ancillary properties.

There has been much debate over whether one β-blocker is superior to another. Specifically, it has been hypothesized that nonselective blockade with carvedilol might produce greater benefits than β_1-selective blockade. This hypothesis is based on observations that the β_1-receptor is downregulated, and the β_2- and α_1-receptors account for a larger proportion of total cardiac adrenergic receptors in the failing heart. Only one trial with a mortality end point has provided a head-to-head comparison of carvedilol and a β_1-selective blocker. The Carvedilol or Metropolol European Trial (COMET) compared carvedilol 25 mg twice daily and immediate-release metoprolol 50 mg twice daily and found a significant 17% lower mortality rate in patients treated with carvedilol.[150] However, concerns regarding the formulation and dose of metoprolol used in COMET limit the conclusions that can be drawn from these findings. Specifically, the study used the immediate-release formulation of metoprolol (metoprolol tartrate), not the sustained-release formulation (metoprolol succinate) shown to reduce mortality. The efficacy of the immediate-release formulation in reducing mortality in heart failure has not been proven. Metoprolol CR/XL provides more consistent plasma concentrations over a 24-hour period and appears to provide more favorable effects on heart rate variability, autonomic balance, and blood pressure, suggesting that this formulation might be superior to immediate-release metoprolol.[151] The target dose of metoprolol also differed between COMET and MERIT-HF. The target dose in COMET was 100 mg/day (50 mg twice daily), whereas the target dose of metoprolol in MERIT-HF was 200 mg/day. Many question whether the degree of β-blockade achieved in COMET with immediate-release metoprolol 50 mg twice daily is comparable to that achieved with metoprolol CR/XL 200 mg/day in MERIT-HF or carvedilol 25 mg twice daily in COMET. Thus, the debate over β-blocker superiority continues, and although some clinicians would argue the superiority of carvedilol, it seems clear that what is most important is that one of the three β-blockers proven to reduce mortality is used.

Adverse Effects Possible adverse effects with β-blocker use in heart failure include bradycardia or heart block, hypotension, fatigue, impaired glycemic control in diabetic patients, bronchospasm in patients with asthma, and worsening heart failure. Clinicians should monitor vital signs and carefully assess for signs and symptoms of worsening heart failure during β-blocker initiation and uptitration. Hypotension is more common with carvedilol due to its α_1-receptor-blocking properties. Bradycardia and hypotension generally are asymptomatic and require no intervention; however, β-blocker dose reduction is warranted in symptomatic patients. Fatigue usually resolves after several weeks of therapy but sometimes requires dose reduction. In diabetic patients, β-blockers may worsen glucose tolerance and can mask the tachycardia and tremor (but not sweating) that accompany hypoglycemia. In addition, nonselective agents such as carvedilol may prolong insulin-induced hypoglycemia and slow recovery from a hypoglycemic episode. Despite this, there is evidence that carvedilol produces better glycemic control in diabetic patients compared with immediate-release metoprolol and may improve insulin sensitivity.[152] Furthermore, carvedilol and metoprolol provide similar survival benefits in patients with concomitant heart failure and diabetes.[153] Diabetic patients should be warned of these potential adverse effects, and blood glucose should be monitored with initiation, adjustment, and discontinuation of β-blocker therapy. Adjustment of hypoglycemic therapy may be necessary with concomitant β-blocker use in diabetics.

Uptitration should be avoided if the patient experiences signs of worsening heart failure, including volume overload and poor perfusion. Fluid overload may be asymptomatic and manifest solely as an increase in body weight. Mild fluid overload may be managed by intensifying diuretic therapy. The treatment of moderate to severe congestion is discussed in Chapter 22. Once the patient has been stabilized, dose titration may continue as tolerated until the target or highest tolerated dose is reached. Despite their negative inotropic effects, continuing β-blocker therapy during hospitalization for

acute heart failure appears to neither worsen symptoms nor delay clinical improvement. In fact, β-blocker withdrawal may increase the risk for mortality after hospital discharge.[154,155] Furthermore, stopping β-blocker therapy during acute decompensation may lead to lower chronic β-blocker use due to failure to reinstitute β-blocker therapy once the patient has stabilized.[155,156] Guidelines recommend continuing β-blocker therapy during hospitalization for heart failure whenever possible.

Absolute contraindications to β-blocker use include uncontrolled bronchospastic disease, symptomatic bradycardia, advanced heart block without a pacemaker, and acute decompensated heart failure. However, β-blockers may be tried with caution in patients with asymptomatic bradycardia or well-controlled asthma. Particular caution is warranted in patients with marked bradycardia (<55 bpm) or hypotension (systolic blood pressure <80 mm Hg). Importantly, concerns of masking symptoms of hypoglycemia or worsening glycemic control should not preclude β-blocker use in patients with diabetes. Indeed, post hoc analysis of heart failure trials shows that β-blockers are well tolerated and significantly reduce morbidity and mortality in patients with diabetes and heart failure.[157] Beta-blockers should be used cautiously in patients with diabetes and recurrent hypoglycemia.

Digoxin Digoxin exerts its positive inotropic effect by binding to sodium- and potassium-activated adenosine triphosphatase (Na,K-ATPase or sodium pump). Inhibition of Na,K-ATPase decreases outward transport of sodium and leads to increased intracellular sodium concentrations. Higher intracellular sodium concentrations favor calcium entry and reduce calcium extrusion from the cell through effects on the sodium—calcium exchanger. The result is increased storage of intracellular calcium in the sarcoplasmic reticulum and, with each action potential, a greater release of calcium to activate contractile elements. Digoxin also has beneficial neurohormonal actions. These effects occur at low plasma concentrations, where little inotropic effect is seen, and are independent of inotropic activity. Unlike other positive inotropes that increase intracellular cyclic adenosine monophosphate (cAMP), digoxin attenuates the excessive SNS activation present in patients with heart failure. Although the precise mechanism is unknown, a digoxin-mediated reduction in central sympathetic outflow and improvement in impaired baroreceptor function appear to play an important role. Because mortality and progression of heart failure are linked to the extent of SNS activation, these sympathoinhibitory effects may be an important component of the clinical response to the drug. Systolic heart failure is also marked by autonomic dysfunction, most notably suppression of the parasympathetic (vagal) system. Digoxin increases parasympathetic activity in patients with heart failure and leads to a decrease in heart rate, thus enhancing diastolic filling. The vagal effects also result in slowed conduction and prolongation of atrioventricular node refractoriness, thus slowing the ventricular response in patients with atrial fibrillation. Because atrial fibrillation is a common complication of heart failure, the combined positive inotropic, neurohormonal, and negative chronotropic effects of digoxin can be particularly beneficial for such patients. The overall response to digoxin is usually an increase in cardiac index and a decrease in PAOP with relatively little change in arterial blood pressure.[105,106,158]

Pharmacokinetics Numerous studies of digoxin pharmacokinetics have been published and are summarized in Table 20–9. Digoxin has a large volume of distribution and is extensively bound to various tissues, most notably to Na,K-ATPase in skeletal and cardiac muscles. Because it does not distribute appreciably to body fat, loading doses of digoxin (when necessary) should be calculated based on estimates of lean body weight. There is a long "distribution phase" after administration of oral or IV digoxin, resulting in a lag time before maximum pharmacologic response is observed (see Table 20–9). Transiently elevated SDCs during the distribution phase are not associated with increased therapeutic or adverse effects, although they can mislead the clinician who is unaware of the timing of blood sampling relative to the previous digoxin dose. Consequently, blood samples for measurement of SDCs should be collected at least 6 hours and preferably 12 hours or more after the last dose.

TABLE 20-9 Clinical Pharmacokinetics of Digoxin

Oral bioavailability	
Tablets	0.5–0.9 (0.65)[a]
Elixir	0.75–0.85 (0.80)
Capsules	0.9–1.0 (0.95)
Onset of action	
Oral	1.5–6 h
Intravenous	15–30 min
Peak effect	
Oral	4–6 h
Intravenous	1.5–4 h
Terminal half-life	
Normal renal function	36 h
Anuric patients	5 d
Volume of distribution at steady state	7.3 L/kg
Fraction unbound in plasma	0.75–0.80
Fraction excreted unchanged in urine	0.65–0.70

Source: Data from Schentag JJ, Bang AJ, Kozinski-Tober JL. Digoxin. In: Burton ME, Shaw LM, Schentag JJ, Evans WE, eds. Applied Pharmacokinetics and Pharmacodynamics: Principles of Therapeutic Drug Monitoring. 4th ed. Baltimore, MD: Lippincott Williams & Wilkins; 2006:410–439.

In patients with normal renal function, 60% to 80% of a dose of digoxin is eliminated unchanged in urine via glomerular filtration and tubular secretion. The terminal half-life of digoxin is approximately 1.5 days in subjects with normal renal function but approximately 5 days in anuric patients (see Table 20–9). Recent evidence indicates that the drug efflux transporter P-glycoprotein (P-gp) plays an important role in the bioavailability, renal and nonrenal clearance, and drug interactions with digoxin. Clinically important pharmacokinetic/pharmacodynamic drug interactions are summarized in Table 20–10. An extensive review of the pharmacokinetics and pharmacodynamics of digoxin is available.[158]

Adverse Effects Digoxin can produce a variety of cardiac and noncardiac adverse effects, but it is usually well tolerated by most patients (Table 20–11).[105,106] Noncardiac adverse effects frequently involve the CNS or GI system but also may be nonspecific (e.g., fatigue or weakness). Cardiac manifestations include numerous different arrhythmias that are believed to be caused by multiple electrophysiologic effects (Table 20–11). Cardiac arrhythmias may be the first evidence of toxicity in a patient (before any noncardiac symptoms occur). Rhythm disturbances are of particular concern because patients with systolic heart failure are already at increased risk of sudden cardiac death, presumably due to ventricular arrhythmias. Patients at increased risk of toxicity include those with impaired renal function and/or decreased lean body mass, the elderly, and those taking interacting drugs. Hypokalemia, hypomagnesemia, and hypercalcemia will predispose patients to cardiac manifestations of digoxin toxicity. Thus, concomitant therapy with diuretics may lead to electrolyte abnormalities and increase the likelihood of cardiac arrhythmias. Similarly, hypothyroidism, myocardial ischemia, and acidosis will increase the risk of cardiac adverse effects. Although digoxin toxicity is commonly associated with plasma concentrations greater than 2 ng/mL, clinicians should remember that digoxin

TABLE 20-10 Selected Digoxin Drug Interactions

Drug	Mechanism/Effecy	Suggested Clinical Management
Amiodarone, dronedarone	Inhibits P-glycoprotein, resulting in decrease in renal and nonrenal clearance; can increase SDC by 70–100%	Monitor SDC and adverse effects; anticipate the need to reduce the dose by 50%
Antacids	Concurrent administration may decrease digoxin bioavailability by 20-35%	Space doses at least 2 h apart or avoid concurrent use if possible
Cholestyramine, colestipol	Bind digoxin in gut and decrease bioavailability 20-35%; may also decrease enterohepatic recycling	Space doses at least 2 h apart or avoid concurrent use if possible
Diuretics	Thiazides or loop diuretics may cause hypokalemia and hypomagnesemia, thereby increasing the risk of digitalis toxicity	Monitor and replace electrolytes if necessary
Erythromycin, clarithromycin, tetracycline	Alter gut bacterial flora; bioavailability and SDC increase 40–100% in about 10% of patients who extensively metabolize digoxin in the gut, may also be due to inhibition of P-glycoprotein by macrolides	Monitor SDC and anticipate the need to reduce the dose; avoid concurrent use if possible
Ketoconazole, itraconazole	Decrease in renal and nonrenal clearance by inhibition of P-glycoprotein; SDC may increase by 50–100%	Monitor SDC and anticipate the need to reduce the dose by 50%
Kaolin-pectin	Large dose (30–60 mL) may decrease digoxin bioavailability by ~60%	Space doses at least 2 h apart or avoid concurrent use if possible
Metoclopramide	Increase in gut mobility may decrease bioavailability of slow-dissolving tablets; unknown significance	Effect is minimized by administration of digoxin capsules
Neomycin, sulfasalazine	Decrease in bioavailability by 20–25%	Space doses at least 2 h apart or avoid concurrent use if possible
Propafenone	Decrease in renal clearance; SDC may increase 30–40%	Monitor SDC and anticipate the need to reduce the dose
Quinidine	Inhibits P-glycoprotein, resulting in decrease in renal and nonrenal clearance; also, displacement of digoxin from tissue-binding sites, with decrease in the volume of distribution; SDC generally increases about twofold	Monitor SDC and adverse effects; anticipate the need to reduce dose by 50%
Spironolactone	Decrease in renal and nonrenal clearance; also, interference with some digoxin assays, thus increasing apparent SDC	Monitor SDC and anticipate the need to reduce dose; check assay for interference
Verapamil	Inhibits P-glycoprotein, resulting in decrease in renal and nonrenal clearance, SDC may increase 70–100%	Monitor SDC and anticipate the need to reduce the dose by 50%; consider using another calcium channel blocker

Abbreviation: SDC, serum digoxin concentration.

toxicity is based on the presence of symptoms rather than a specific plasma concentration.[158] Usual treatment of digoxin toxicity includes drug withdrawal or dose reduction and treatment of cardiac arrhythmias and electrolyte abnormalities. In patients with life-threatening digoxin toxicity, purified digoxin-specific Fab antibody fragments should be administered. Serum digoxin concentrations will not be reliable until the antidote has been eliminated from the body.[106]

TABLE 20-11 Signs and Symptoms of Digoxin Toxicity

Noncardiac (mostly CNS) adverse effects
Anorexia, nausea, vomiting, and abdominal pain
Visual disturbances:
Halos, photophobia, problems with color perception (i.e., red-green or yellow-green vision), and scotomata
Fatigue, weakness, dizziness, headache, neuralgia, confusion, delirium, and psychosis
Cardiac adverse effects[a,b]
Ventricular arrhythmias
Premature ventricular depolarizations, bigeminy, trigeminy, ventricular tachycardia, ventricular fibrillation
AV block
First-degree, second-degree (Mobitz type I), or third-degree
AV junctional escape rhythms, junctional tachycardia
Atrial arrhythmias with slowed AV conduction or AV block
Particularly paroxysmal atrial tachycardia with AV block
Sinus bradycardia

[a]Some adverse effects may be difficult to distinguish from the signs/symptoms of heart failure.
[b]Digoxin toxicity has been associated with almost every known rhythm abnormality (only the more common manifestations are listed).
Abbreviation: AV, atrioventricular.

Pharmacoeconomic Considerations

Heart failure imposes a tremendous economic burden on the healthcare system. In patients over age 65, it is the most common reason for hospitalization, with hospital admission rates for this disorder continuing to increase. Heart failure is also associated with unacceptably high readmission rates during the 3 to 6 months after initial discharge. Current estimates of costs of heart failure treatment in the United States approach $40 billion, with most of the costs associated with hospitalization.[1,3] The prevalence of heart failure and the costs associated with patient care are expected to increase as the population ages and as survival from ischemic heart disease improves. Thus, approaches to improve the quality and cost-effectiveness of care for these patients may have a significant impact on healthcare costs.

Studies to assess the cost-effectiveness of drug therapy for heart failure have been recently reviewed.[159] Many studies provide direct cost estimates demonstrating an economic value when employing standard heart failure therapies, specifically ACE inhibitors, β-blockers, and digoxin. Much of the economic benefit of these therapies is due to a reduction in hospitalization. Although the clinical and economic benefits of these therapies are well recognized, standard heart failure therapies are often underprescribed or underdosed, which may increase the risk of poor clinical outcomes.[61] For example, a recent observational analysis of a heart failure quality improvement initiative found that only 32.5% of over 12,000 patients who were admitted to the hospital for heart failure and met guidelines for aldosterone antagonist therapy received these agents at discharge.[98]

More recent pharmacoeconomic studies have focused on the impact of newer heart failure therapies or those used as alternatives to standard therapy. ARBs have been shown to be cost-effective in patients not receiving ACE inhibitors.[160] Eplerenone has been

shown to be a cost-effective therapy in patients with post-MI heart failure.[161] Fixed-dose combination hydralazine and ISDN is cost-effective in African American patients with severe heart failure.[162] Other cost-effective studies have focused on device therapy. Both prophylactic ICD implantation in patients with systolic dysfunction and CRT therapy appear to be cost-effective.[163,164] However, cost-effectiveness is limited if devices are implanted in patients with any comorbid illnesses that may shorten life expectancy.

As the management of heart failure has become increasingly complex, the development of disease management programs approaches that use multidisciplinary teams has been studied extensively. These programs utilize several broad approaches, including heart failure specialty clinics, home-based interventions, and close patient follow-up. Most are multidisciplinary and may include physicians, advanced practice nurses, dietitians, and pharmacists. In general, the programs focus on optimization of drug and no-drug therapy, patient and family education and counseling, exercise and dietary advice, intense follow-up by telephone or home visits, encouragement of self-care, and monitoring and management of signs and symptoms of decompensation.[1] Such programs have typically focused on patients with more severe heart failure who are at high risk of hospital admission. In general, multidisciplinary disease management programs improve quality of life and reduce heart failure and all-cause hospitalizations and costs, although these benefits are not consistently demonstrated in all studies.[165,166]

11 Pharmacists can play an important role in the multidisciplinary team management of heart failure.[39,167,168] Compared with conventional treatment, pharmacist interventions, which included medication evaluation and therapeutic recommendations, patient education, and follow-up telephone monitoring, reduced hospitalizations for heart failure, adverse drug events, and medication errors. Adherence to guideline-recommended therapy was also improved by pharmacist intervention. A recent study found that pharmacist intervention improved medication adherence and reduced emergency department visits and hospitalizations in low-income patients with heart failure.[168] Thus, the role and cost benefits of pharmacist involvement in the multidisciplinary care of patients with heart failure are now apparent and should include optimizing doses of heart failure drug therapy, screening for drugs that exacerbate heart failure, monitoring for adverse drug effects and drug interactions, educating patients, and patient follow-up. The role of pharmacists in optimizing pharmacotherapy is underscored by the finding that heart failure is associated with an increased risk of experiencing adverse drug reactions.[169]

CURRENT CONTROVERSIES

Diabetes is a frequently occurring comorbidity in patients with heart failure. Metformin is effective for reducing the microvascular and macrovascular complications of diabetes. The use of metformin in patients with heart failure is controversial because of the potential risk for lactic acidosis. However, recent observational studies show that metformin is commonly used by many clinicians and that it may be safe and effective in this population. Prospective data are needed to determine the benefits and risks of metformin in patients with heart failure.

Inflammation plays a key role in the pathophysiology of heart failure. Because of their pleiotropic actions, there is great interest in the use of statins in patients with heart failure. Despite significant decreases in LDL cholesterol, two recent well-designed clinical trials failed to demonstrate that statins improved clinical outcomes.[31,32] Because coronary artery disease is a frequent cause of heart failure, many clinicians still use statins in patients with both disorders in the belief that these agents reduce cardiovascular risk.

EVALUATION OF THERAPEUTIC OUTCOMES

Although mortality is an important end point, it does not give a complete measure of the overall impact of heart failure because many patients are hospitalized repeatedly for heart failure exacerbations and continue to survive, albeit with a significantly reduced quality of life. Thus, some of the more important therapeutic outcomes in heart failure management, such as prolonged survival or prevention or slowing of the progression of heart failure, cannot be quantified in an individual patient. However, after appropriate diagnostic evaluation to determine the etiology of heart failure, ongoing clinical assessment of patients typically focuses on three general areas: (a) evaluation of functional capacity, (b) evaluation of volume status, and (c) laboratory evaluation.

The evaluation of functional capacity should focus on the presence and severity of symptoms the patient experiences during activities of daily living and how his or her symptoms affect these activities. Questions directed toward the patient's ability to perform specific activities may be more informative than general questions about the symptoms the patient may be experiencing. For example, patients should be asked if they can exercise, climb stairs, get dressed without stopping, check the mail, go shopping, or clean the house. Another important component of assessment of functional capacity is to ask patients what activities they would like to do but are now unable to perform.

Assessment of volume status is a vital component of the ongoing care of patients with heart failure. This evaluation provides the clinician important information about the adequacy of diuretic therapy. Because the cardinal signs and symptoms of heart failure are caused by excess fluid retention, the efficacy of diuretic treatment is readily evaluated by the disappearance of these signs and symptoms. The physical examination is the primary method for the evaluation of fluid retention, and specific attention should be focused on the patient's body weight, extent of JVD, presence of hepatojugular reflux, presence and severity of pulmonary congestion, and peripheral edema. Specifically, in a patient with pulmonary congestion, monitoring is indicated for resolution of rales and pulmonary edema and improvement or resolution of dyspnea on exertion, orthopnea, and PND. For patients with systemic congestion, a decrease or disappearance of peripheral edema, JVD, and hepatojugular reflux is sought. Other therapeutic outcomes include an improvement in exercise tolerance and fatigue and a decrease in nocturia and heart rate. Clinicians also will want to monitor blood pressure and ensure that the patient does not develop symptomatic hypotension as a result of drug therapy. Body weight is a sensitive marker of fluid loss or retention, and patients should be counseled to weigh themselves daily, reporting changes to their healthcare provider so that adjustments can be made in diuretic doses. It should be noted that, particularly with β-blocker therapy, symptoms may worsen initially and that it may take weeks to months of treatment before patients notice improvement in symptoms. Also, patients and healthcare providers should be aware that heart failure progression may be slowed even though symptoms have not resolved.

Routine monitoring of serum electrolytes and renal function is required in patients with heart failure. Assessment of serum potassium is especially important because hypokalemia is a common adverse effect of diuretic therapy and is associated with an increased risk of arrhythmias and digoxin toxicity. Serum potassium monitoring is also required because of the risk of hyperkalemia associated with ACE inhibitors, ARBs, and aldosterone antagonists. A serum potassium ≥4 mEq/L should be maintained, with some evidence suggesting it should be ≥4.5 mEq/L.[170] Assessment of renal function (BUN and serum creatinine) is also an important end point for monitoring diuretic and ACE inhibitor therapy. Common causes

TABLE 20-12 ACC/AHA Clinical Performance Measures for Adults with Systolic Heart Failure

Performance Measure	Recommendation
Inpatient measures	
Evaluation of left ventricular systolic function[a]	Echocardiogram with Doppler flow studies is the most useful test, as it enables clinicians to determine the presence of pericardial, myocardial, or valvular abnormalities. Patients with LVEF <40% should be considered for specific therapy (e.g., ACE inhibitors, β-blockers). Class I recommendation, Level of Evidence C.
ACE inhibitors or ARBs for patients with left ventricular systolic dysfunction[a]	Patients with LVEF <40% or moderate or severe systolic dysfunction should receive an ACE inhibitor or ARB unless contrainidcations are present or there is a history ot intolerance to both drugs. ACE inhibitors: Class I recommendation, Level of Evidence A. ARBs: Class 1, Level of Evidence A.
Anticoagulant therapy with warfarin for patients with atrial fibrillation	Patients without contraindications should receive warfarin to reduce the risk of a thromboembolic event. Class I recommendation, Level of Evidence A.
Discharge instructions[a]	Patients discharged home should receive written instructions that address activity levels, diet, discharge medications, follow-up appointments, weight monitoring, and what to do if symptoms worsen. Education of both patients and families is important.
Smoking cessation counseling[a]	All current or recent smokers should receive counseling on smoking cessation and offered smoking cessation pharmacotherapy. Class I recommendation, Level of Evidence C.
Outpatient measures	
Initial laboratory evaluation	Laboratory tests may identify the cause of or factors that may exacerbate heart failure. Recommended tests include complete blood count, urinalysis, serum electrolytes, BUN, serum creatinine, blood glucose, liver function, TSH. Class I, Level of Evidence C.
Evaluation of left ventricular systolic function	Echocardiogram with Doppler flow studies is the most useful test, as it enables clinicians to determine the presence of pericardial, myocardial, or valvular abnormalities. Patients with LVEF <40% should be considered for specific therapy (e.g., ACE inhibitors, β-blockers). Class I recommendation, Level of Evidence C.
Weight measurement	Important measure for assessment and follow-up of patient's volume status. Helps determine the need for adjustment of diuretic therapy. Class I recommendation, Level of Evidence C.
Blood pressure measurement	Hypertension is an important risk factor for heart failure development and progression. Class I recommendation, Level of Evidence C.
Assessment of clinical symptoms of volume overload	Along with weight, plays an important role in determining the need for adjustment of diuretic therapy. Assess for the presence of orthopnea and dyspnea. Orthostatic blood pressure evaluation should also be performed. Class I recommendation, Level of Evidence C.
Assessement of clinical signs of volume overload	Assessment of the presence of the following signs should be performed: peripheral edema, rales, hepatomegaly, ascites, jugular venous pressure, S_3 and S_4 gallop. Class I recommendation, Level of Evidence C.
Assessment of activity level	Longitudinal assessment of functional capacity allows for determination of whether symptoms are improving and serve as basis for additional treatment decisions. Class I recommendation, Level of Evidence C.
Patient education	Patients should be provided with written and/or verbal instructions at one or more visits on the following: weight monitoring, diet (sodium restriction), symptom management, physical activity, smoking cessation, medication instruction, minimizing or avoiding NSAIDs, referral to educational/disease management programs, prognosis/end-of-life issues. Class I recommendation, Level of Evidence C.
Beta-blocker therapy	All patients with stable heart failure and LVEF <40% should receive treatment with one of the three β-blockers proven to reduce mortality unless contraindicated. Class I recommendation, Level of Evidence A.
ACE inhibitors or ARBs for patients with left ventricular systolic dysfunction	Patients with LVEF <40% or moderate or severe systolic dysfunction should receive an ACE inhibitor or ARB unless contraindications are present or there is a history ot intolerance to both drugs. ACE inhibitors: Class I recommendation, Level of Evidence A. ARBs: Class I recommendation, Level of Evidence A.
Warfarin therapy for patients with atrial fibrillation	Patients without contraindications should receive warfarin to reduce the risk of a thromboembolic event. Class I recommendation, Level of Evidence A.

[a]Also Center for Medicare and Medicaid Services and the Joint Commission Core Measures.

Abbreviations: ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BUN, blood urea nitrogen; LVEF, left ventricular ejection fraction; NSAID, nonsteroidal antiinflammatory drug; TSH, thyroid-stimulating hormone.

Source: Adapted from Bonow RW, Bennett S, Casey DE, et al. ACC/AHA clinical performance measures for adults with systolic heart failure: A report of the American College of Cardiology/American Heart Association Task Force on Performance Measures (Writing Committee to Develop Heart Failure Clinical Performance Measures). of worsening renal function in patients with heart failure include overdiuresis, adverse effects of ACE inhibitor or ARB therapy, and hypoperfusion.

Most of these therapeutic end points are incorporated into the ACC/AHA performance measures outlined in Table 20–12.

ABBREVIATIONS

ACC: American College of Cardiology

ACE: angiotensin-converting enzyme

AHA: American Heart Association

ANP: atrial natriuretic peptide

ARB: angiotensin receptor blocker

AVP: arginine vasopressin

BNP: B-type natriuretic peptide

cAMP: cyclic adenosine monophosphate

CNP: C-type natriuretic peptide

CO: cardiac output

COX-2: cyclooxygenase-2

CRT: cardiac resynchronization therapy

ESC: European Society of Cardiology

HFSA: Heart Failure Society of America

IABP: intra-aortic balloon pump

ICD: implantable cardioverter-defibrillator

JVD: jugular venous distention

LVAD: left ventricular assist device
LVEDP: left ventricular end-diastolic pressure
LVEDV: left ventricular end-diastolic volume
LVEF: left ventricular ejection fraction
MI: myocardial infarction
NSAID: nonsteroidal antiinflammatory drug
NYHA: New York Heart Association
PAOP: pulmonary artery occlusion pressure
P-gp: P-glycoprotein
RAAS: renin—angiotensin—aldosterone system
SDC: serum digoxin concentration
SNS: sympathetic nervous system
SVR: systemic vascular resistance
TNF-α: tumor necrosis factor-α
TZD: thiazolidinedione

CHAPTER 21

Diastolic Heart Failure and the Cardiomyopathies

JEAN M. NAPPI AND ROBERT L. PAGE II

KEY CONCEPTS

1. Diastolic heart failure is a frequent cause of heart failure (35–50% prevalence) and has a significant effect on mortality (25–35% 5-year mortality rate) and morbidity (50% 1-year readmission rate).
2. Hypertension is a common cause of diastolic heart failure.
3. The diagnosis of diastolic heart failure can be made when a patient has both symptoms and signs of congestive heart failure on physical examination and preserved left ventricular (LV) function.
4. Treatment should be targeted at symptom reduction, causal clinical disease, and underlying basic mechanisms. Patients with diastolic heart failure may be treated differently than those with systolic dysfunction.
5. Nonpharmacologic treatment measures include weight loss, smoking cessation, dietary changes, and exercise.
6. Symptom-targeted therapy includes decreasing pulmonary venous pressure, maintaining atrial contraction and atrioventricular synchrony, and reducing heart rate. Exercise tolerance is increased by reducing exercise-induced increases in blood pressure and heart rate.
7. Disease-targeted therapy includes preventing or treating myocardial ischemia and preventing or regressing LV hypertrophy.
8. Treatment strategies for patients with hypertrophic cardiomyopathy (HCM) are aimed at improving symptoms and preventing sudden cardiac death.
9. Patients with HCM who are at high risk for sudden cardiac death should receive an implantable cardioverter-defibrillator.
10. Patients with HCM who are symptomatic may benefit from β-blockade or verapamil.

DIASTOLIC HEART FAILURE

Heart failure (HF) may be caused by a primary abnormality in systolic function, diastolic function, or both. Making the distinction is important because the prevalence, prognosis, and treatment of HF may be quite different depending on whether the predominant mechanism causing the symptoms is systolic or diastolic dysfunction. Clinical studies have reported that up to 74% of patients with HF have preserved left ventricular ejection fraction (LVEF), variably defined as exceeding 40%, 45%, or 50%.[1–3] When patients with preserved EF exhibit symptoms consistent with effort intolerance and dyspnea, especially in the presence of venous congestion and edema, the term *diastolic heart failure* (DHF) is often used.[4] Despite recognition of its importance, no strong consensus exists regarding appropriate terminology for this syndrome; therefore, the terms DHF, HF with preserved EF, and HF with normal EF are often used synonymously.

DHF can be defined as a condition in which myocardial relaxation and filling are impaired and incomplete. The ventricle is unable to accept an adequate volume of blood from the venous system, does not fill at low pressure, and/or is unable to maintain normal stroke volume. In its most severe form, DHF results in overt symptoms of HF. In modest DHF, symptoms of dyspnea and fatigue occur only during stress or activity, when heart rate and end-diastolic volume increase. In its mildest form, DHF can be manifested as a slow or delayed pattern of relaxation and filling with little or no elevation in diastolic pressure and few or no cardiac symptoms. The congestive symptoms that occur with DHF are a manifestation of increased pulmonary venous pressures. DHF is caused by impaired myocardial relaxation and/or increased diastolic stiffness. When HF is caused by a predominant abnormality in diastolic function, the ventricular chamber is not enlarged, and EF may be normal or even elevated.[5] Figure 21–1 shows the pressure—volume relationship in a patient with normal versus abnormal diastolic function. Changes in the myocardium are associated with a shift upward and to the left of the pressure—volume curve, so that for any increase in LV volume, diastolic pressure rises to a much greater level than normally would occur. Clinically, patients present with reduced exercise tolerance and dyspnea when they have elevated LV diastolic

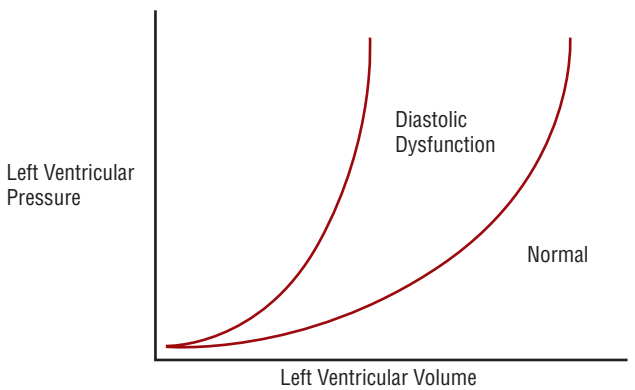

FIGURE 21-1. Diastolic pressure—volume relationship in a normal patient (*right trace*) and a patient with diastolic dysfunction (*left trace*).

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

pressures. Patients with DHF have a predominant abnormality in diastolic function, whereas patients with systolic heart failure (SHF) have a predominant abnormality in systolic function of the LV. Furthermore, patients with DHF are more likely to be female, obese, have diabetes, and be hypertensive.[1]

EPIDEMIOLOGY

1 Recent studies suggest that as many as half of all patients presenting with overt HF have preserved EF.[7,8] The prevalence of DHF depends on a number of determinants: patient age, patient gender, study design, particular population under consideration, and EF. It is important to recognize that these determinants are not independent but interdependent. The most important determinant appears to be patient age. DHF is relatively uncommon in young and middle-aged patients. The prevalence of DHF increases with age, approximating 15% in patients younger than 60 years, 35% in patients between 60 and 70 years, and 50% in patients older than 70 years. Prospective community-based studies showed that in patients older than 70 years, the prevalence of DHF approaches 50%.[9,10] As the proportion of the population older than 65 years continues to grow, it has been estimated that DHF may eventually become the most common form of HF.[11]

ETIOLOGY

2 Several disorders can impair ventricular function and play a role in the development of DHF. DHF is seen often in patients with hypertension, coronary artery disease (CAD), valvular heart disease, atrial fibrillation, diabetes, and hypertrophic cardiomyopathy (HCM).[12,13] Hypertension and valvular heart disease are common underlying cardiovascular disorders in patients with DHF.[14] There are several proposed mechanisms by which hypertension may impair diastolic function. Hypertension can alter diastolic function through its effects on wall tension, myocardial hypertrophy and fibrosis, and small-vessel structure and function, as well as by predisposing to epicardial CAD. An association between impaired LV filling and subnormal high-energy phosphate metabolism has been shown in hypertensive patients, even in the absence of left ventricular hypertrophy (LVH).[15]

LVH plays a central role in the adaptation of the myocardium to pressure overload. Severe and long-standing pressure overload has been associated with phenotypic alterations at the myocyte level, which differs from the physiologic hypertrophy seen in athletes.[16] Long-term chronic pressure overload stimulates cardiac growth and collagen production, which lead to an increase in myocardial mass and structural remodeling. The results of these changes are an increase in myocardial stiffness and a decrease in diastolic filling.

PATHOPHYSIOLOGY

The pathologic disease processes that cause DHF include myocardial ischemia with or without epicardial CAD, pressure overload hypertrophy, and genetic hypertrophy. HCM is a prototype for DHF. The grossly thickened myocardium, structural changes, and interstitial fibrosis severely alter the passive elastic properties of the myocardium. Patients with HCM and LV outflow obstruction are sensitive to small changes in volume, such that a small decrease in filling pressure can lead to a decrease in LV end-diastolic volume and a dramatic fall in stroke volume and cardiac output.

The basic mechanisms by which pressure-overload hypertrophy and genetic hypertrophy cause DHF include extramyocardial factors and factors intrinsic to the myocardium, such as changes in the cardiac muscle cell and in the extracellular matrix that surrounds the cardiomyocyte (Table 21–1).[17–19] Intracellular processes, such as changes in calcium homeostasis, contractile and noncontractile proteins, energetics, and the cytoskeleton, contribute to abnormalities in myocardial relaxation and stiffness. Changes in the extracellular matrix, particularly changes in fibrillar collagen, alter relaxation and stiffness. In addition to the cardiomyocyte and the extracellular matrix, local myocardial neuroendocrine activation can impair relaxation and increase stiffness. Activation of neurohormones such as the renin—angiotensin—aldosterone system (RAAS) may act directly to alter diastolic properties or act indirectly by altering calcium homeostasis. Finally, extramyocardial changes in loading conditions and changes in heterogeneity occur in hypertrophied ventricles and contribute to changes in relaxation and stiffness, so that even when the myocardium itself is normal, changes in these extramyocardial factors can cause abnormalities in diastolic function.[19]

TABLE 21-1 Potential Pathologic Mechanisms of Diastolic Heart Failure

Mechanisms directly affecting myocardial tissue	
Cardiomyocyte	Increased intracellular calcium, producing calcium overload
	Myofilaments
	Increased troponin C calcium binding and increased myofilament calcium sensitivity
	Cytoskeleton
	Changes in cytoskeletal proteins
	Energetics
	Decrease in ATP availability, leading to decreased rate or extent ofactomyosin dissociation
Extracellular matrix	Increased content of fibrillar collagen
	Thickening of existing fibrillar collagen
	Decreased MMP and/or increased TIMP
Neurohormones	Increased renin–angiotensin–aldosterone
	Increased endothelin
Extramyocardial mechanisms	
Increased hemodynamic load: preload or afterload	
Increased heterogeneity	
Systemic neurohormones	Increased levels of angiotensin II
Pericardium	Pericardium may have a constraining effect as LV filling pressure and end-diastolic volume increase

ATP = adenosine triphosphate, LV = left ventricular, MMP = matrix metalloproteinase, TIMP = tissue inhibitor of MMP

Myocardial ischemia, particularly in the subendocardial region, is common when ventricular hypertrophy is present. Slow or delayed myocardial relaxation and perivascular fibrosis can adversely affect coronary blood flow and coronary blood flow reserve. This may contribute to the development of myocardial ischemia and sudden death.[20,21] Therefore, myocardial ischemia may be part of the clinical syndrome of DHF even if no epicardial CAD is present.

An association between diabetes and diastolic dysfunction leading to heart failure has been identified.[22] This may occur even in the absence of atherosclerotic heart disease. Hyperinsulinemia is thought to trigger cardiac hypertrophy, and hyperglycemia alters the expression and function of the intracellular receptors, ultimately leading to systolic and diastolic dysfunction.

CLINICAL PRESENTATION OF DIASTOLIC DYSFUNCTION

General

- The majority of patients do not show symptoms at rest but in response to stress conditions. Symptoms may be induced or worsened by physical exercise but also by events such as anemia, fever, tachycardia, and systemic pathologies.

Symptoms

- The patient may complain of exertional dyspnea, orthopnea, paroxysmal dyspnea, and exercise intolerance.

Signs

- Pulmonary congestion (rales)
- Exaggerated rise in blood pressure and heart rate in response to exercise
- Presence of an S4 gallop

Laboratory Tests

- B-type natriuretic peptide and N-terminal pro–B-type natriuretic peptide will be elevated.

Other Diagnostic Tests

- Two-dimensional echocardiography will show a normal or elevated EF, normal or decreased cardiac output, and LVH and/or concentric remodeling.
- Doppler echocardiography will show elevated pulmonary venous pressures.
- Chest radiography will show pulmonary congestion.
- Electrocardiography may reflect LVH.

DIAGNOSIS

3 The criteria used to make the diagnosis of DHF remain controversial. However, making an accurate diagnosis is extremely important. Guidelines from the European Society of Cardiology (ESC) propose that three requirements must be present to make the diagnosis of DHF: (a) symptoms or signs of HF; (b) normal or only mildly abnormal systolic function (EF exceeding 45–50%); and (c) abnormal diastolic function (e.g., abnormal relaxation, filling, distensibility, or stiffness).[23] The first two requirements appear to be well justified;the third requirement may not be.[6]

Three clinical factors have been proposed to categorize patients with DHF: the presence/absence of elevated blood pressure or history of hypertension, the presence/absence of LVH, and the presence/absence of increased LV volume.[22] Based on these factors, patients are divided into four subgroups according to the underlying pathophysiology: HCM, infiltrative or restrictive cardiomyopathy, increased preload, and abnormal ventricular-arterial coupling.

With few exceptions, DHF cannot be distinguished from SHF on the basis of the history, physical examination, chest x-ray, and electrocardiogram (ECG) alone. The frequency with which patients have symptoms and signs of HF on physical examination or chest x-ray is not dependent on whether they have SHF or DHF.[21] Patients with DHF are often elderly, hypertensive women.[1,22]

The data from a number of studies demonstrate that signs and symptoms of HF do not predict EF. In contrast, they do predict the presence of increased LV diastolic pressure. The question then becomes whether the increase in LV diastolic pressure occurs in association with normal LV volume and EF, as would occur in DHF, or whether the increase in LV diastolic pressure occurs in association with an increased LV volume and decreased EF, as would occur with SHF. Therefore, determining whether HF is caused by systolic or diastolic dysfunction requires some estimate of LV size and EF. These measurements can be made using echocardiography, radionuclide ventriculography, or contrast ventriculography. When a patient presents with dyspnea, pulmonary rales, and radiographic evidence of pulmonary venous hypertension, the detection of normal LV end-diastolic volume and normal EF supports the diagnosis of DHF. Conditions such as mitral stenosis, pulmonary disease, sleep apnea, anemia, cirrhosis, hypothyroidism, and drug-induced fluid retention must be ruled out because they can cause similar symptoms.[24]

B-type natriuretic peptide (BNP) and its biologically inactive fragment, N-terminal proBNP (NT-proBNP), are cardiac neurohormones secreted from the myocardium in response to increases in ventricular volume and pressure. Both are used as an aid in the differential diagnosis of dyspnea. The Breathing Not Properly study evaluated 452 patients with echocardiography within 30 days of an emergency department visit. Of the 452 patients, 165 (36.5%) had EF >45% (mean EF 59%).[25] In these patients with preserved EF who had been admitted to the hospital for dyspnea, BNP levels were significantly lower than those found in patients with SHF (413 vs 821 pg/mL). However, there was considerable overlap in the BNP levels in patients with DHF compared with those without HF, making BNP levels less useful. Furthermore, the sensitivity, specificity, and predictive accuracy of BNP levels in DHF are limited in part because BNP is altered by age, adiposity, gender, and other factors. Similar findings have been documented with NT-proBNP. In a study of 68 symptomatic patients with isolated DHF (EF >50%), NT-proBNP was significantly increased in patients with isolated DHF and correlated with disease severity. Compared with conventional echocardiography, Doppler imaging, and heart catheterization, NT-proBNP exhibited the best negative predictive value for detection of DHF.[26]

PROGNOSIS

The prognosis in patients with DHF, although less ominous than in those with SHF, is worse than that of age-matched control patients. The 5-year mortality rate of these patients approximates 25%, although mortality rates as high as 13% over a 6-month period have been reported.[1,7] In comparison, the annual mortality rate of patients with SHF approximates 10% to 15%, whereas age-matched control mortality approaches 1%. However, in a population-based cohort study of 2,802 patients with HF, no significant difference was demonstrated in the adjusted 1-year mortality rate for patients with EF <40% compared with those with EF >50%.[27] Unfortunately, compared with SHF, little improvement in the survival rate among patients with DHF has been seen.[11]

In patients with DHF, the prognosis is also affected by the clinical pathologic etiology causing the disease. When patients with CAD are excluded, the annual mortality rate for DHF is 2% to 3%. In addition to the clinical pathologic etiology causing HF, other predictors of mortality are impaired renal function ≤60 mL/min/m^2, worse functional class (New York Heart Association [NYHA] class III—IV), male gender, and older age (>74 years).[28,29]

The mode of death appears similar in patients with systolic versus diastolic HF. Sudden death and death from progressive pump failure occurred with equal frequency in patients with SHF as those with DHF. Morbidity also is similar between patients with SHF and DHF. The 1-year hospital readmission rate can approach 50%, thereby placing significant pressure on healthcare resources. However, patients with DHF appear to have a higher risk of nonfatal myocardial infarction (MI) and stroke.[12,27]

TREATMENT

Diastolic Heart Failure

The general principles used to guide the treatment of SHF are based on numerous large, randomized, double-blind, multicenter trials. Until recently, no such randomized trials had been performed in patients with DHF. Consequently, the guidelines for the management of DHF are based primarily on clinical investigations in relatively small groups of patients, clinical experience, and concepts

TABLE 21-2 Targeted Approach to Treatment of Diastolic Heart Failure

Symptom-targeted treatment	Rationale	Agent
Decrease pulmonary venous pressure	Reduce left ventricular volume Reduce heart rate	Diuretics, nitrates, salt restriction
Decrease myocardial oxygen consumption	Control blood pressure	β-blockers, diltiazem, verapamil ACE inhibitors, angiotensin receptor blockers, calcium channel blockers
Maintain atrial contraction	Restore and/or maintain sinus rhythm	Cardioversion of atrial fibrillation
Improve exercise tolerance	As above	Use positive inotropic agents with caution
Disease-targeted treatment		
Prevent/treat myocardial ischemia		β-blockers, diltiazem, verapamil, nitrates
Prevent/regress ventricular hypertrophy		Antihypertensive therapy
Mechanism-targeted treatment		
Modify myocardial and extramyocardial mechanisms		Possibly ACE inhibitors or angiotensin receptor blockers, diuretics, spironolactone
Modify intracellular and extracellular mechanisms		Possibly ACE inhibitors or angiotensin receptor blockers, spironolactone

ACE = angiotensin-converting enzyme

based on the knowledge and understanding of the pathophysiology of the disease process. The treatment regimen outlined in Table 21–2 applies to patients with DHF who have clear manifestations of congestion either at rest or with exertion. Whether treatment of asymptomatic diastolic dysfunction confers any benefit has not been demonstrated.

DESIRED OUTCOME

4 Treatment should be targeted at reducing symptoms, principally those of increased pulmonary venous pressure. It should include decreasing diastolic pressure by decreasing LV volume, maintaining atrial contraction, and reducing heart rate without reducing cardiac output. Also, treatment should be targeted at the pathologic diseases that cause DHF. For example, CAD, hypertensive heart disease, and aortic stenosis have relatively specific therapeutic targets, such as lowering blood pressure, inducing LVH regression, performing aortic valve replacement, and treating ischemia by increasing myocardial blood flow and reducing myocardial oxygen demand. Finally, treatment should be targeted at the underlying mechanisms that are altered by the disease processes just mentioned.[30]

NONPHARMACOLOGIC THERAPY

Diet and Lifestyle

5 The initial effort in the treatment of DHF is aimed at decreasing symptoms. The first step in this effort is to decrease pulmonary congestion by decreasing LV volume using sodium and fluid restriction. A low-sodium diet (≤2 g/day) and moderate fluid restriction will help to prevent volume overload. Both sodium and fluid restriction must be done with care. Excessive restriction can lead to hypotension, low-output state, and/or renal insufficiency. Daily weights may help to assess volume status. Dietary and lifestyle factors that decrease the risk of development of epicardial CAD and high blood pressure should be encouraged.[23,31]

Moderate aerobic exercise to improve cardiovascular conditioning is beneficial to maintain a slower heart rate, improve cardiac reserve, and maintain skeletal muscle function. Isometric exercise should be avoided.[32]

Interventional/Surgical Procedures

An important step in symptom-targeted therapy that acts to decrease pulmonary venous pressures is to maintain atrial contraction and atrioventricular (AV) synchrony. Maintaining atrial contraction and AV synchrony is important both in preserving normal cardiac output and in keeping LV diastolic pressure low. Chemical or electrical cardioversion of persistent atrial tachyarrhythmias will decrease diastolic pressure, increase cardiac output, and resolve pulmonary edema. An AV sequential pacemaker should be used to treat bradyarrhythmias in patients requiring pacing.

Therapy also should be aimed at preventing or treating the underlying pathologic cause of DHF. Aortic valve replacement should be performed in symptomatic patients with pressure-overload hypertrophy caused by aortic stenosis. Revascularization should be performed in selected patients with DHF caused by CAD-induced myocardial ischemia. In addition, myocardial oxygen consumption and myocardial blood flow should be increased using medical treatment, including nitrates, β-blockers, and calcium channel blockers.[33]

Indications for Hospitalization

Patients with DHF may present with an acute onset of pulmonary edema. Potential causes for the acute decompensation of these patients include volume overload, uncontrolled hypertension, acute myocardial ischemia, progressive valvular disease (aortic stenosis), and new-onset or uncontrolled tachyarrhythmias. Treatment strategies for these patients eventually may include the need for surgery, as in the case of valvular disease.

The initial management focuses on relieving pulmonary congestion and maintaining oxygenation. IV diuretic agents and nesiritide for patients are effective for volume overload. Caution must be exercised to avoid overdiuresis or excessive lowering of LV end-diastolic volume, which can lead to a decrease in stroke volume. Morphine and nitroglycerin also are effective in reducing LV end-diastolic pressure.[34]

PHARMACOLOGIC TREATMENT

Drug Treatments of First Choice

With a few notable exceptions, many of the drugs used to treat SHF are the same as those used to treat DHF. However, the rationale for their use, the pathophysiologic process that is being altered by the drug, and the dosing regimen may be entirely different depending on whether the patient has SHF or DHF. For example, β-blockers are recommended for the treatment of both SHF and DHF. In DHF, however, β-blockers are used to decrease heart rate, increase diastolic duration, and modify the hemodynamic response to exercise. In SHF, β-blockers are used in the long run to increase the inotropic state and modify LV remodeling. Diuretics also are used in the treatment of both SHF and DHF. However, the doses of diuretics used to treat DHF are, in general, much smaller than the doses used to treat SHF. Antagonists of the

TABLE 21-3 Evidence-Based Pharmacotherapy for Diastolic Heart Failure

Recommendations	Recommendation Grade[a]
Diuretics	
• A loop or a thiazide diuretic should be considered for patients with volume overload. However, with more severe volume overload or inadequate response to a thiazide, a loop diuretic should be implemented. Caution is warranted not to lower preload excessively, which may reduce stroke volume and cardiac output.	C
ACE inhibitors	
• ACE inhibitors may be considered in all patients.	C
• ACE inhibitors should be considered in all patients who have symptomatic atherosclerotic cardiovascular disease or diabetes and one additional risk factor.	C
Angiotensin receptor blockers	
• Angiotensin receptor blockers may be considered in all patients.	C
• In patients who are intolerant of ACE inhibitors, an angiotensin receptor blocker can be considered an alternative.	C
β-Blockers	
• β-blockers should be considered in patients with one or more of the following conditions:	
Myocardial infarction	A
Hypertension	B
Atrial fibrillation requiring ventricular rate control	B
Calcium channel blockers	
• In patients with atrial fibrillation warranting ventricular rate control who either are intolerant to or have not responded to a β-blocker, diltiazem or verapamil should be considered.	C
• A nondihydropyridine or dihydropyridine calcium channel blocker can be considered for symptom-limiting angina.	A
• A nondihydropyridine or dihydropyridine calcium channel blocker can be considered for hypertension.	C

[a]Strength of recommendations: A, randomized controlled clinical trials; B, cohort and case control studies based on observations from observational studies or registries, post hoc, subgroup, and meta-analysis; C, expert opinion, epidemiologic findings from observational studies, and safety findings from large-scale use.

ACE = angiotensin-converting enzyme

Data from Heart Failure Society of America. Evaluation and management of patients with heart failure and preserved left ventricular ejection fraction. J Card Fail 2010;16:e126–133.

RAAS are useful in lowering blood pressure and reducing LVH. Some drugs, however, are used to treat either SHF or DHF but not both. Calcium channel blockers such as diltiazem, nifedipine, and verapamil have little utility in the treatment of SHF. In contrast, each of these drugs has been proposed as being useful in the treatment of DHF.

Published Guidelines

Much less objective information on the treatment of DHF is available. This relative paucity of objective information is reflected in guidelines for the diagnosis and management of HF published by the American College of Cardiology (ACC)/American Heart Association (AHA), the ESC, and the Heart Failure Society of America (HFSA).[23,31,36] In general, all three guidelines recommend treating comorbid conditions by controlling heart rate and blood pressure, alleviating causes of myocardial ischemia, reducing volume, and restoring and maintaining sinus rhythm. Table 21–3 summarizes the therapeutic recommendations from the HFSA.

General Information

Although dozens of trials evaluating pharmacologic therapy have been conducted in patients with SHF, few trials have focused on patients with DHF. In fact, most published HF trials have specifically excluded patients with preserved EF. A few published large clinical studies and several trials examining various agents in the treatment of DHF are under way (Table 21–4). With these studies and others that are currently under way, an evidence-based treatment for DHF will be defined.

Alternative Drug Treatment

As a result of the controversy regarding the diagnosis of DHF, the development and design of large clinical trials have been hindered. At this time, most antihypertensive agents would be acceptable forms of therapy for hypertensive heart disease, with the exception of α-blockers (e.g., doxazosin). In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the doxazosin treatment arm was dropped because patients randomized to doxazosin had an increased risk for developing HF and stroke compared with the chlorthalidone arm.[37]

Special Populations

DHF is associated with hypertension and aging, making it a common diagnosis in elderly white women. Because these women often are frail and have low muscle mass, their creatinine clearance and renal function may be compromised. Special care must be taken when selecting and titrating doses of drugs, monitoring levels of serum creatinine and electrolytes, and using diuretics, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin receptor blockers.[38]

Diabetes is often a comorbid condition in patients with HF. Because the thiazolidinediones (pioglitazone and rosiglitazone) are associated with fluid retention, caution is warranted when initiating these drugs in patients with a history of DHF. Thiazolidinediones should be discontinued in patients with symptoms related to volume overload.[3,36]

DRUG CLASS INFORMATION

Diuretics

6 Diuretics can provide symptom-targeted therapy by decreasing systemic and LV volume. By decreasing LV diastolic volumes, LV pressures slide down the curvilinear diastolic pressure—volume relationship toward a lower, less steep portion of the curve. As pressure throughout diastole falls, mean diastolic pressure, pulmonary capillary wedge pressure, and pulmonary venous pressure fall. These agents effectively reduce the central blood volume and lower diastolic pressures, thus alleviating the symptoms of the congestive state. Diuretics can provide disease-targeted therapy by decreasing blood pressure and favorably affecting the myocardial oxygen supply versus demand ratio. Lower LV diastolic pressures may increase subendocardial blood flow, preventing or alleviating the imbalance

TABLE 21-4 Completed and Ongoing Large Clinical Trials for Diastolic Heart Failure

Trial (No. of Patients)	Treatment	Inclusion Criteria	Primary End Point	Results
DIG Ancillary Study[53] (n = 988)	Digoxin vs placebo for a mean of 37 months. Patients received ACE inhibitor (86%) and diuretics (85%).	EF >45%, NYHA II–IV, normal sinus rhythm	Composite of HF hospitalization or HF mortality	No significant difference was found in the primary end point between treatment groups (HR = 0.82, P = 0.136). Digoxin had no effect on all-cause mortality or cause-specific mortality or on all-cause or CV hospitalization. Compared with placebo, digoxin use was associated with a trend toward a reduction in HF hospitalizations (HR = 0.79, P = 0.094) and an increase in unstable angina admissions (HR = 1.37, P = 0.061).
CHARM-Preserved[13] (n = 3,023)	Candesartan vs placebo for a mean of 36.6 months. Patients continued their background HF medications: ACE inhibitor (19%), β-blocker (55%), diuretics (75%), spironolactone (11%).	EF >40%, NYHA II–IV, ≥1 hospitalization for CV reason	Composite of CV mortality or HF hospitalization	No significant difference was found in the primary end point between treatment groups (adjusted HR = 0.86, P = 0.051) or in CV deaths (adjusted HR = 0.95, P = 0.635). Compared with placebo, candesartan use was associated with fewer HF admissions (P = 0.047), lower incidence of new diabetes (HR = 0.60, P = 0.005), and a reduction in the composite of CV death, hospitalization for HF, MI, and stroke (adjusted HR = 0.86, P = 0.037).
PEP-CHF[47] (n = 850)	Perindopril vs placebo for a mean of 2.1 years	Clinical criteria for HF, EF ≥40%, age ≥70 years	Composite of total mortality and HF hospitalization	At 1 year and at study completion, no significant difference was found in the primary end point between treatment groups (HR = 0.69, P = 0.055; HR = 0.70, P = 0.545). In a subgroup analysis, patients ≤75 years of age (HR = 0.29, P = 0.035) and with a history of MI (HR = 0.38, P = 0.004) showed a reduction in the primary end point. Compared with placebo, perindopril use at 1 year was associated with fewer unplanned hospital admissions (HR = 0.63, P = 0.033), greater improvements in exercise tolerance (P = 0.011), and improvement in NYHA class (P = 0.030).
I-Preserve[49] (n = 4,128)	Irbesartan vs placebo for 2 years. ACE inhibitor can be used for any indication other than HTN.	Clinical criteria for HF or hospitalized within 6 months for HF, age ≥60 years, NYHA II–IV, EF ≥45%	Composite of all-cause mortality or CV hospitalization	No significant difference was found in the primary end point between treatment groups (HR = 0. 95, P = 0.35), overall death rates (HR = 1.00, P = 0.98), or CV hospitalization rate (HR = 0.95, P = 0.44).
J-DHF[73] (n = 800)	Carvedilol vs placebo for 2 years	Clinical criteria for HF, EF >40%	Composite of CV mortality and unplanned HF hospitalization	Expected to be completed in 2010
SENIORS[43] (n = 2,111)	Nebivolol vs placebo for 21 months	Clinical criteria for HF with either documented heart failure hospitalization with 1 year or documented EF ≤35% within 6 months, age ≥70 years	All-cause mortality or cardiovascular hospitalization	In the study, 1,359 patients (64%) had an EF ≤35% (mean 28.7%), and 752 (36%) had an EF >35% (mean 49.2%). In patients with EF >35%, the HR for nebivolol vs placebo for the primary end point was 0.81 (P = 0.104). No significant difference existed between groups (EF ≤35% vs EF >35%, P = 0.720).
TOPCAT[74] (n = 4,500)	Spironolactone vs placebo for 2 years	Clinical criteria for HF, age ≥50 years, EF ≥45%, ≥1 hospitalization for HF, controlled SBP	CV mortality, aborted cardiac arrest, HF hospitalization	Expected to be completed in 2011

ACE = angiotensin-converting enzyme; CHARM = Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity; CV = cardiovascular; DIG, Digitalis Investigational Group; EF = ejection fraction; HF, heart failure; HR, hazard ratio; HTN, hypertension; I-Preserve = Irbesartan in Heart Failure with Preserved EF; J-DHF: Japanese Diastolic Heart Failure Study; MI, myocardial infarction; NYHA, New York Heart Association; PEP-CHF = Perindopril for Elderly Persons with Chronic Heart Failure; SBP, systolic blood pressure; SENIORS, Study of Effects of Nebivolol Intervention on Outcomes and Rehospitalization in Seniors with Heart Failure; TOPCAT = Trial of Aldosterone Antagonist Therapy in Adults with Preserved Ejection Fraction Congestive Heart Failure

between myocardial oxygen supply and demand (see Fig. 21–1). Diuretics alone and especially in combination with other antihypertensive drugs are an effective approach to therapy.

In a small subpopulation of ALLHAT, admissions for 1,367 patients hospitalized for heart failure were adjudicated in a centrally blinded manner.[39] In this study, signs and symptoms of HF were similar between patients with reduced and preserved EF. Treatment with chlorthalidone significantly reduced the risk for hospitalization in patients with preserved EF when compared with amlodipine, lisinopril, or doxazosin (hazard ratio 0.69, 0.74, and 0.53, respectively). After the onset of HF symptoms, patients with a preserved EF had a better prognosis when compared with patients with a reduced EF; however, the long-term outcome is still poor.

Treatment with diuretics should be initiated at low doses in order to avoid hypotension and fatigue. Hypotension can be a significant problem in the treatment of DHF because these patients have a very steep LV diastolic pressure—volume curve such that a small change in volume causes a large change in filling pressure and cardiac output. After the acute treatment of DHF has been completed, long-term treatment should include small to moderate oral

doses of diuretics (furosemide 20 to 40 mg/day, chlorthalidone 25 to 100 mg or hydrochlorothiazide 12.5 to 25 mg/day). If prompt and sustained diuresis is not achieved, the dosage of a single diuretic should be increased, or a loop and thiazide or thiazide-like diuretic should be used in combination. Aldosterone antagonists such as spironolactone and eplerenone may be especially effective for long-term use because of their potassium-sparing effects and because their antagonism of RAAS activation may alter intramyocardial and extramyocardial mechanisms, causing abnormalities in diastolic function.[40] Because aldosterone is profibrotic and stimulates hypertrophy, aldosterone blockade may be of benefit in patients with DHF and is under investigation in TOPCAT (Trial of Aldosterone Antagonist Therapy in Adults with Preserved Ejection Fraction Congestive Heart Failure).[41]

Torsemide may also offer a benefit beyond diuresis. In a small, open-label trial in patients with diastolic and systolic heart failure, torsemide in comparison to furosemide was shown to decrease two different indices of fibrillar collagen turnover and myocardial fibrosis.[42] These findings are interesting, but clinical importance remains to be established.

Excessive diuresis may result in hypotension, low-output syndrome, and worsening renal insufficiency. Electrolyte imbalances, including hypokalemia and hypomagnesemia, are common with diuretics. Carbohydrate intolerance and hyperuricemia are dose-related adverse drug reactions seen with thiazide diuretics. Thiazide diuretics generally are ineffective in patients with a creatinine clearance <30 mL/min. Spironolactone can cause hyperkalemia and gynecomastia. Eplerenone may be used as an alternative to spironolactone in patients who complain of gynecomastia. In general, diuretic agents are very cost-effective in the management of DHF.

Nitrates

7 Similar to diuretics, nitrates can provide symptom-targeted therapy by acting to decrease LV volume by increasing venous capacitance. In addition, nitrates can provide disease-targeted therapy by providing antiischemic effects in patients with DHF due to CAD.

Like diuretics, therapy should be initiated at low doses to avoid hypotension. Isosorbide dinitrate 10 mg three or four times daily, isosorbide mononitrate (Imdur) 30 mg daily, nitroglycerin paste 0.5 to 1 inch every 4 to 6 hours, and nitroglycerin patch 0.1 to 0.2 mg/h applied each day are common initial doses. Doses can be increased during long-term therapy and titrated against symptoms. Nitrate tolerance has not been studied in this patient population but probably occurs. Like diuretics, nitrates can cause hypotension and a low-output syndrome. Headaches are common but may be less frequent with continued use.

Sublingual nitroglycerin tablets or nitroglycerin spray may be used for patients who develop shortness of breath with mild exercise, and they can be used much in the same way as in patients with ischemic symptoms. Nitroglycerin will decrease LV end-diastolic volume, resulting in relief of breathlessness.

Beta-Adrenergic Blockers

Beta-blockers can provide symptom-targeted therapy by decreasing heart rate and can provide disease-targeted therapy by treating high blood pressure and CAD. By decreasing heart rate and increasing the duration of diastole, β-blockers can help to lower and maintain low pulmonary venous pressures. Tachycardia is poorly tolerated in patients with DHF for several reasons. First, rapid heart rates cause an increase in myocardial oxygen demand and a decrease in coronary perfusion time. This rapid rate can promote ischemic diastolic dysfunction even in the absence of epicardial CAD, especially in patients with LVH. Second, incomplete relaxation between cardiac cycles may result in an increase in diastolic pressure relative to volume. Thus, LV distensibility is reduced. Third, a rapid rate reduces diastolic filling time and ventricular filling. Fourth, hearts with diastolic dysfunction exhibit a flat or even negative relaxation rate versus frequency relationship. Thus, as heart rate increases in these hearts, relaxation does not become augmented and may become slower and incomplete, causing diastolic pressures, especially early in diastole, to increase.[9] For these and other reasons, most clinicians use β-blockers (and calcium channel blockers) to prevent excessive tachycardia and produce a relative bradycardia in patients with diastolic dysfunction. However, excessive bradycardia can result in a fall of cardiac output despite an increase in LV filling. Such considerations underscore the need for individualizing therapeutic interventions that affect heart rate. Although the optimal heart rate must be individualized, an initial goal might be a resting heart rate of approximately 60 beats/min, with a blunted exercise-induced increase in heart rate not to exceed 110 beats/min.[9]

No evidence suggests a specific therapeutic advantage of one β-blocker over another. Selective and nonselective β-blockers appear equally effective in DHF. Interestingly, a subanalysis of the SENIORS (Study of Effects of Nebivolol Intervention on Outcomes and Rehospitalization in Seniors with Heart Failure) trial showed a similar response to nebivolol in patients with preserved and reduced EF.[43]

In a small prospective cohort analysis, patients with DHF prescribed β-blockers had improved survival compared with those not receiving β-blocker therapy at hospital discharge.[44] Furthermore, in a community-based registry, carvedilol use had similar 1-year mortality rates in patients with preserved and reduced EF but less reduction in hospitalizations for patients with a reduced EF.[45]

In general, it is not necessary to start the drug at an extremely low dose and titrate the β-blocker in a slow, progressive fashion in DHF as it is in SHF. However, because patients tend to be older, have numerous comorbidities, and take concomitant medications, it is prudent to start with a moderate dose of β-blockers. Doses such as metoprolol tartrate 25 mg twice daily, metoprolol succinate 25 mg daily, atenolol 25 mg daily, carvedilol 3.125 mg twice daily, and nebivolol 1.25 mg daily titrated to a higher dose with a treatment target of a heart rate of approximately 60 beats/min can be considered.

Prinzmetal vasospastic angina, occlusive peripheral vascular disease, diabetes mellitus type 1 that is prone to hypoglycemia, severe heart block, and excessive bradycardia are contraindications to β-blockers. Beta-blockers may be considered in patients with reactive airway disease or asymptomatic bradycardia but should be used with extreme caution. The main side effects of β-blockers are depression, fatigue, bradycardia, bronchospasm, and impotence. Many of the β-blockers are eliminated via hepatic metabolism and may be affected by other drugs that either inhibit (e.g., cimetidine and verapamil) or enhance (e.g., barbiturates) hepatic enzymes. Because the doses are titrated to patient response, these interactions are managed easily.

Calcium Channel Blockers

Calcium channel blockers can provide symptom-targeted treatment by decreasing heart rate and increasing exercise tolerance. They can provide disease-targeted treatment by treating high blood pressure and CAD. However, the beneficial effect of these agents on exercise tolerance is not always paralleled by improved LV diastolic function or increased relaxation rate. Nonetheless, a number of small clinical trials have shown that the use of these agents results in both short- and long-term improvement in exercise capacity in patients with DHF.[30,35]

Of the calcium channel blockers, the nondihydropyridines (verapamil and diltiazem) are the most effective because they lower heart rate in addition to lowering blood pressure.[22] Sustained-release nifedipine, because of its strong vasodilator properties, tends to cause hypotension and reflex tachycardia. In addition, nifedipine causes peripheral edema. These characteristics make it less useful in DHF. Amlodipine may be effective because it reduces blood pressure. Initial doses are verapamil 120 to 240 mg/day, diltiazem 90 to 120 mg/day, and amlodipine 2.5 mg/day.

Heart block is a contraindication for the nondihydropyridines. The most common side effects are bradycardia and heart block (for the nondihydropyridines). Peripheral edema and headache also are common. Nondihydropyridines exacerbate the bradycardic effects of β-blockers, and verapamil raises digoxin serum concentrations by 70%. Diltiazem raises cyclosporine, tacrolimus, and sirolimus serum concentrations. IV calcium salts inhibit the pharmacologic effect of calcium channel blockers. Generic formulations or similar products, but not necessarily generic equivalents to the original brand names, are available for some of the calcium channel blockers.

Neurohormonal Antagonists

Both basic and clinical studies suggest that DHF is associated with activation of systemic and local cardiac neuroendocrine systems such as the RAAS. One mechanism causing fluid retention and the increases in central and systemic volume in patients with DHF is activation of these neuroendocrine systems. Therefore, treatment of DHF could include agents such as angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, and aldosterone antagonists that attenuate the fluid retention caused by neuroendocrine activation. In addition to promoting fluid retention, neuroendocrine activation can have direct effects on cellular and extracellular mechanisms that contribute to the development of DHF. Modulation of neuroendocrine activation may provide mechanism-targeted treatment by decreasing fibroblast activity and interstitial fibrosis, improving intracellular calcium handling, and decreasing myocardial stiffness. Finally, the RAAS antagonists provide disease-targeted treatment by treating hypertension.[18,46]

The mechanisms that evoke activation of the neuroendocrine system remain incompletely understood in patients with DHF. A number of factors have been suggested. Myocardial ischemia, uncontrolled hypertension, and excessive dietary sodium or sodium-retaining medications may contribute to neuroendocrine activation. Limited distensibility of the atria may attenuate the secretion of atrial natriuretic factor and thereby reduce its diuretic effect. In others, low systemic vascular resistance and/or low arterial pressure may contribute to an increase in RAAS activation and salt and water retention. Elevated venous pressure may cause renal sodium retention directly. The reduction in blood volume that follows the use of diuretics triggers an increase in sympathetic tone and further activation of the RAAS. Such neurohormonal activation can lead to vasoconstriction and a worsening of the congestive state. Some vasodilators, particularly nitrates and pure arteriolar vasodilators, evoke a similar response. By contrast, ACE inhibitors, aldosterone antagonists, and β-blockers blunt neurohormonal activation and decrease the salt and water retention that complicates the treatment of HF.

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors can provide symptom-targeted treatment by decreasing LV volume and directly improving relaxation. They can provide disease-targeted treatment by treating high blood pressure, preventing LVH, promoting regression, and preventing fibrosis. Treatment of high blood pressure with ACE inhibitors has been shown to normalize load, prevent and/or regress LVH, correct the abnormality in intracellular processes, and modify the extracellular matrix response.[46]

The largest study with an ACE inhibitor, the Perindopril for Elderly Persons with Chronic Heart Failure (PEP-CHF) trial, failed to find a significant effect on clinical outcomes at 1 year in patients with DHF who received perindopril (see Table 21–4). Based on these limited data, it appears that ACE inhibitors may improve HF symptomatology and exercise capacity while not impacting mortality.[47]

At this time, no evidence suggests an advantage of one ACE inhibitor over another. Their effects appear to be a class effect. Initial doses should be small to moderate to avoid hypotension, especially if the patient examination does not indicate volume overload. Examples of initial starting doses are captopril 6.25 mg three times daily, enalapril 2.5 mg/day, and lisinopril 2.5 mg/day.

A history of angioedema and pregnancy are contraindications to ACE inhibitors. Hyperkalemia, persistent cough, hypotension, taste disturbances, and worsening renal function are common side effects but are managed by decreasing the dose or discontinuing the drug.

Angiotensin Receptor Blockers

Angiotensin receptor blockers can provide symptom-targeted treatment by decreasing LV pressure, decreasing LV volume, and increasing exercise tolerance. They can provide disease-targeted treatment by lowering blood pressure. The Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity (CHARM)-Preserved trial (see Table 21–4) was the first large prospective study to demonstrate some benefit of an angiotensin receptor blocker in patients with preserved EF currently receiving the usual treatment.[13] However, in a cost analysis study of the CHARM program using European data, there was a net increase in the daily cost of care in the CHARM-Preserved trial.[48] In addition, 22% of candesartan-treated patients discontinued therapy because of hypotension ($P = 0.009$), increased serum creatinine ($P = 0.0005$), and hyperkalemia ($P = 0.029$).

In the I-PRESERVE (Irbesartan in Heart Failure with Preserved EF) trial, irbesartan was compared with placebo in over 4,000 patients with symptoms of heart failure and an EF of at least 45%.[49] There was no significant difference between irbesartan and placebo with regard to death or hospitalization for cardiovascular causes. No benefit was seen in quality-of-life measures. There was a high discontinuation rate of the study drug in this trial (33%), as well as a high rate of postrandomization initiation of ACE inhibitors (20%) and spironolactone (10%), that may have contributed to the outcome in this trial.

Angiotensin receptor blockers may be used as antihypertensive agents in patients with DHF. Initial doses of candesartan start at 4 mg/day, irbesartan 150 mg/day, losartan 25 mg/day, telmisartan 40 mg/day, and valsartan 80 mg/day. As with the ACE inhibitors, angiotensin receptor blockers are contraindicated in pregnancy. The side effects of angiotensin receptor blockers are similar to those of ACE inhibitors, but they are not associated with persistent cough.

Aldosterone Antagonists

Aldosterone antagonists can provide improved myocardial functioning by decreasing LV volume and chamber stiffness.[50,51] They can provide disease-targeted treatment by decreasing the fibrosis that accompanies LVH. An analysis of the Randomized Aldactone Evaluation Study (RALES) found that spironolactone significantly decreased the levels of serum markers for cardiac collagen turnover. The benefit from spironolactone was seen in patients with higher levels of collagen synthesis markers. This was the first study to show that serum levels of markers of cardiac collagen synthesis were associated with a poor clinical outcome and could be decreased with spironolactone. This property distinguishes spironolactone

from other diuretics that have no effect on myocardial necrosis or collagen turnover.

Like other diuretics, spironolactone should be initiated at a low dose and increased to treat symptoms. Spironolactone may be initiated at doses of 12.5 to 25 mg/day. It should be avoided in patients with severe renal failure. Hyperkalemia and gynecomastia are the most common side effects. Eplerenone is a viable alternative to spironolactone in patients complaining of sex hormone—related side effects and may be initiated at 25 mg/day.[40]

Positive Inotropic Agents

Positive inotropic agents, such as β-agonists and phosphodiesterase inhibitors, are generally not used in the treatment of patients with isolated DHF because LVEF is preserved, and there appears to be little potential for a beneficial effect. Such agents have the potential to worsen DHF by adversely affecting energetics, inducing ischemia, raising heart rate, and inducing arrhythmias.[9] In contrast to long-term use, positive inotropic drugs may be beneficial in the short-term treatment of pulmonary edema associated with DHF. These agents can enhance sarcoplasmic reticular function, promote more rapid and complete relaxation, increase splanchnic blood flow, increase venous capacitance, and facilitate diuresis.[9] However, they should be used with caution, if they are used at all, because the risk-to-benefit ratio is not clearly established.

Istaroxime is an investigational agent with inotropic and lusitropic properties. It was evaluated in acutely hospitalized patients with systolic heart failure (mean EF 27%).[52] In addition to lowering pulmonary capillary wedge pressure, istaroxime was found to decrease diastolic stiffness. Whether this property would be useful in patients with a preserved EF presenting with acute decompensation is unknown at this time.

Digitalis Derivatives

Digoxin, by inhibiting the Na^+,K^+-adenosine triphosphatase (ATPase) pump, augments intracellular calcium and thereby augments contractile state. In this manner, digoxin produces an increase in systolic energy demands while adding to a relative calcium overload in diastole. These effects may not be apparent clinically under many circumstances, but during hemodynamic stress or ischemia, digoxin may promote or contribute to diastolic dysfunction.[9] However, based on the data from the Digitalis Investigational Group (DIG) Ancillary Study (see Table 21–4), it appears that digoxin has, at most, a very limited role in the management of patients with DHF in normal sinus rhythm.[53]

PHARMACOECONOMIC CONSIDERATIONS

Frequent admission to the hospital is common in patients with DHF. Five-year cost estimates associated with HF are similar in patients with a preserved EF and those with a reduced EF.[54] Because DHF is primarily a disease of the elderly, comorbid conditions will create challenges in any trial design. When developing a pharmacotherapeutic plan, cost to the patient should be carefully considered because adherence to an antihypertensive regimen is paramount to a beneficial outcome.

CLINICAL CONTROVERSIES

- Digoxin may increase hospitalizations for unstable angina in patients with DHF and normal sinus rhythm.
- Antihypertensive drugs that antagonize the RAAS may be preferred for patients with DHF.

EVALUATION OF THERAPEUTIC OUTCOMES

The end points used in assessing effective therapies for DHF include mortality, hospitalization for worsening HF, functional status or quality-of-life indicators, and cost. Other end points may target underlying mechanisms of disease, such as calcium homeostasis and regression of fibrosis. A paucity of data exits regarding the most effective regimen for DHF.

CARDIOMYOPATHIES

Diastolic dysfunction plays a role in the presentation of some types of cardiomyopathy. Over the past decade, the terminology and classification used for the cardiomyopathies have been confusing because of overlap among the diseases and/or classification schemes. In 2006, the ACC/AHA suggested a broader definition for the cardiomyopathies. The expert panel defined the cardiomyopathies as

> a heterogeneous group of diseases of the myocardium associated with mechanical and/or electrical dysfunction that usually (but not invariably) exhibit inappropriate ventricular hypertrophy or dilation and are due to a variety of causes that frequently are genetic. Cardiomyopathies either are confined to the heart (primary cardiomyopathy) or are part of generalized systemic disorders (secondary cardiomyopathy), often leading to cardiovascular death or progressive HF-related disability.[55]

The primary cardiomyopathies are further divided into genetic, mixed (genetic and nongenetic), and acquired. Endocrine conditions, inflammation, metabolic disorders, infiltrative diseases, and toxins are a few of the causative factors of secondary cardiomyopathy.[55] It is important to note that this new contemporary classification does not include pathologic myocardial processes that are a direct result of other cardiovascular conditions, such as valvular heart disease, hypertension, and CAD. Therefore, ischemic cardiomyopathy is not considered a "true" cardiomyopathy.

Frequently, a specific etiology is not evident. Therefore, another commonly used categorization of the cardiomyopathies is based on the structural and/or functional abnormalities present. The three groups of primary cardiomyopathies usually are described as dilated, hypertrophic, or restrictive. An understanding of the pathophysiologic basis for each type of cardiomyopathy leads to a rational selection of drug therapy or other treatment modality. The characteristics for each of the types of cardiomyopathy are listed in Table 21–5. The distinction among the cardiomyopathies is not absolute, and there is some overlap in their functional abnormalities.

In dilated cardiomyopathy, the cardinal feature is ventricular chamber enlargement. Systolic function is abnormal with normal LV wall thickness, leading to a decreased cardiac output. In patients with hypertrophic cardiomyopathy (HCM), the ventricular cavity is not dilated, but the ventricular muscle mass is increased, existing in the absence of known causes of LVH. Ventricular cavity size is normal or decreased, and systolic function often is preserved. Patients with HCM may have an obstructive or nonobstructive form. Patients with restrictive cardiomyopathy have inadequate ventricular compliance, causing diastolic dysfunction as a result of endocardial and/or myocardial disease. The clinical presentation is similar to that of constrictive pericarditis.

HYPERTROPHIC CARDIOMYOPATHY

HCM is a primary, genetic cardiomyopathy that is inherited as an autosomal dominant trait caused by mutations in any of 12 genes. The distribution of the hypertrophy usually is asymmetric, meaning that segments of the LV are thickened to varying degrees. There also may be enlargement of the atria, thickening of the mitral valve leaflets, and fibrotic areas within the ventricular wall. In the past, the terms *idiopathic hypertrophic subaortic stenosis* and *hypertrophic*

TABLE 21-5 Characteristics of the Cardiomyopathies

	Dilated	Hypertrophic	Restrictive
Myocardial mass	↑→↑↑	↑↑↑	nl→↑
Ventricular cavity size	↑↑↑↑↑	↓↓→nl	nl→↓

LV filling pressure	↑↑	nl→↑	↑
Chest x-ray film	Moderate to marked cardiac enlargement	Mild to moderate cardiac enlargement	Mild cardiac enlargement
Electrocardiogram	ST-segment and T-wave abnormalities	ST-segment and T-wave abnormalities, LV hypertrophy	Low voltage, conduction defects
Echocardiogram	LV dilation and dysfunction	Asymmetric septal hypertrophy, systolic anterior motion of the mitral valve	Increased LV wall thickness possible
Radionuclide studies	LV dilation and dysfunction	Vigorous systolic function	Normal systolic function

↑ = increased, ↓ = decreased, LV = left ventricular, nl = normal

obstructive cardiomyopathy were used to describe patients with HCM and outflow obstruction.

Epidemiology

Recent epidemiologic investigations estimate the prevalence of phenotypically expressed HCM in the general adult population to be approximately 0.2% (1:500), making it the most frequently occurring cardiomyopathy. HCM is the most common genetic cardiovascular disease and the most common cause of sudden death in young athletes.[56] More than 430 mutations in 12 genes have been identified to date; however, many individuals with a mutant gene go undetected.[57]

Etiology

The genetic predisposition to HCM is thought to be an autosomal dominant trait with variable penetrance. Because of the wide variability of presentation, not all cases in a family may be detected. HCM usually is caused by mutations in the genes for β-myosin heavy chain, myosin-binding protein C, and cardiac troponin T.[58]

Pathophysiology

HCM appears to have several different pathophysiologic mechanisms leading to similar clinical manifestations, although the prognoses for patients will vary. The pathophysiology of HCM is a complex relationship among several factors, including (a) asymmetric LVH, (b) diastolic dysfunction, (c) dynamic obstruction of the outflow tract, and (d) myocardial ischemia. Each of these components contributes to the overall presentation of the patient to a varying degree.[56,58]

Left Ventricular Hypertrophy The hypertrophy seen in HCM usually is diffuse and involves the septum and LV anterolateral free wall to a greater degree than the posterior segment. Asymmetric septal hypertrophy is a sensitive marker for HCM but is not specific for this disorder. In patients with outflow obstruction, the basal septum usually is markedly thickened at the level of the mitral valve. In patients with nonobstructive HCM, the outflow tract is larger, and the septal hypertrophy that occurs has a more distal or apical distribution.[59]

Cellular disorganization is a common histologic finding in HCM. Morphologic abnormalities are found at the gross, microscopic, and ultrastructural levels. The disarray of myocytes may contribute to diastolic and systolic dysfunction, as well as serving as a nidus for ventricular arrhythmias. The degree of LVH is associated with a worse clinical course. The presence of hypertrophy correlates directly with myocardial infarction, HF, stroke, and ventricular arrhythmias. Spirito and Autore found that the magnitude of LVH was directly related to the risk of sudden cardiac death.[56]

Diastolic Dysfunction Diastolic dysfunction is the most common abnormality found in patients with HCM. Approximately 80% of patients exhibit symptoms associated with diastolic dysfunction. Studies of the LV led to the realization that diastolic dysfunction is the result of abnormalities in relaxation, distensibility (compliance), and filling. The abnormalities of diastolic function can be both regional and global and lead to an incoordination of contraction and relaxation. Beta-adrenergic stimulation can aggravate these abnormalities, whereas β-receptor blockade may diminish them.[58]

Abnormalities in filling are also associated with changes in chamber stiffness that occur in HCM. This stiffness may be the result of myocardial fibrosis, cellular disorganization, or increased myocardial mass. The decreased distensibility leads to an abnormally steep slope of the diastolic pressure—volume curve, such that an increase in LV volume results in a disproportionate increase in diastolic pressure.

Myocardial relaxation is an energy-dependent process that is sensitive to episodes of ischemia. Diastolic resequestration of calcium ions by the sarcoplasmic reticulum is an energy-dependent process. In the event of ischemia, the sequestration of calcium is inhibited, allowing the calcium to continue its interaction with the myofibrillar contractile proteins. Calcium channel blockers have been used with some success in patients with diastolic dysfunction.[57]

Systolic Function and Outflow Tract Obstruction Abnormalities of systolic function also occur in patients with HCM. The hypertrophied LV may cause a powerful but sometimes uncoordinated contraction presumably as a result of the abnormal architecture of the myocardium. The increase in LV wall thickness results in decreased wall stress during systole. Therefore, the LV contracts against a decreased afterload so that the LV is described as being hyperdynamic. EF often is increased.

Over the past 5 decades, controversy has surrounded the issue of the importance of outflow tract obstruction in conjunction with HCM. The presence of a gradient (the systolic pressure difference between the body and the outflow tract of the LV) is indicative of a dynamic obstruction of the LV outflow tract. Outflow tract gradients occur in approximately 30% to 50% of patients with HCM.[57] The obstruction that occurs usually shows spontaneous variability and may be reduced by interventions that decrease myocardial contractility. The gradient can be augmented by factors that increase contractility (Table 21–6). LV outflow tract obstruction at rest has been found to be a predictor of progression to severe HF symptoms, stroke, and death. It is important to identify and treat these gradients aggressively with medications, surgery, or alcohol septal ablation procedures.[60]

Myocardial Ischemia Chest pain in the absence of CAD is a common symptom of patients with HCM. However, it is appropriate to consider typical CAD in patients with HCM if they have the usual risk factors for atherosclerosis.[61,62] Several mechanisms are proposed for the myocardial ischemia seen in this patient population. There may be inadequate capillary density in relation to the increased LV muscle mass. The small intramural coronary arteries may be abnormally narrowed or excessively compressed during

systole. Impaired relaxation during diastole may inhibit blood flow to the subendocardium. Once myocardial ischemia develops, further increases in LV filling pressure may occur, which, in turn, lead to more ischemia. Repeated episodes of ischemia may be responsible for progressive myocyte loss and fibrosis. The subendocardium is at greatest risk for ischemic damage because of the lower capillary density and higher oxygen demand secondary to wall tension.

CLINICAL PRESENTATION OF HYPERTROPHIC CARDIOMYOPATHY

General

- The clinical presentation varies widely, ranging from no symptoms to severe symptoms of angina, HF, and sudden death. The severity of symptoms corresponds to the degree of LVH, but this relationship is not absolute.

Symptoms

- The patient may complain of dyspnea, chest pain, fatigue, palpitations, presyncope, and syncope.

Signs

- Systolic murmur

Other Diagnostic Tests

- Echocardiography will show increased myocardial mass.
- Electrocardiography will reveal LVH with or without ST-segment and T-wave abnormalities.

Diagnosis

Making the diagnosis of HCM may be difficult because the disorder may be confused with CAD, aortic stenosis, or mitral regurgitation. Patients with HCM can be young and physically active. The physical signs of the cardiac examination depend on the presence of a systolic pressure gradient within the LV. If a gradient is present, a late-onset systolic murmur is often heard. The murmur is intensified by standing and the Valsalva maneuver and lessened with squatting or hand grip. Very rarely, some patients develop an end-stage LV dilation and a declining LVEF, which often are confused with idiopathic dilated cardiomyopathy. HCM should be considered in the differential diagnosis in patients with HF and unexplained LVH, significant heart murmurs, unexplained syncope, abnormal electrocardiogram patterns (pseudoinfarction or giant negative T waves), or a positive family history.[57]

Echocardiography is used to confirm the diagnosis. The diagnosis of HCM is made with two-dimensional echocardiography, with the usual criterion of LV wall thickness ≥15 mm. Magnetic resonance imaging of the entire LV may add valuable information, especially if the echocardiogram is of suboptimal quality.[55,61]

The development of or increase in a murmur suggests progression of disease, but disappearance of a murmur does not imply improvement. In fact, disappearance of a murmur may herald further impairment of systolic function. Some patients will progress to congestive heart failure (CHF) as a result of atrial fibrillation, mitral regurgitation, or myocardial infarction. If SHF develops, the patient has a poor prognosis.

Contemporary methods of diagnosis consist of genotype assessment. Genetic testing allows for a definitive diagnosis and precise identification of mutations in myocardial sarcomere proteins. Unfortunately, screening for more than 200 mutations in multiple genes is complex, time consuming, and costly. Although becoming more common, therapeutic decisions based on genetic testing are not recommended. Genetic testing is useful in identifying at-risk relatives for potential follow-up and treatment.[63]

Prognosis

The clinical course for a patient with HCM should be viewed in terms of the specific subtypes of the disease spectrum. Patients fall into one of several relatively discrete pathways: (a) high risk for sudden death; (b) symptoms of DHF, including syncope; (c) progression toward advanced end-stage HF; and (d) atrial fibrillation and its sequelae. Of major concern is the incidence of sudden cardiac death among patients with HCM. Approximately 10% to 20% of patients with HCM are at increased risk for sudden death. The mechanism responsible for sudden cardiac death is thought to be related to an electrically unstable myocardium leading to complex ventricular arrhythmias. Less often, sudden death may be the result of hemodynamic changes. The onset of atrial fibrillation in the face of severe LV diastolic dysfunction may result in a significant decrease in stroke volume. This decrease in cardiac output could lead to acute LV failure, MI, or sudden death. Sudden death can be a complication, especially in young athletes with HCM. It is recommended that young patients with HCM refrain from competitive athletics.[55,61]

Quantification of the risk of sudden death remains elusive for patients with HCM. The clinical markers associated with an increased risk for sudden death (Table 21–7) have a high negative predictive value. The absence of all these markers can be used to develop a profile for a patient at low risk for sudden death. The magnitude of hypertrophy appears to be a strong predictor, with the cumulative risk nearly zero for patients with a wall thickness ≤19 mm. Young patients with severe hypertrophy (wall thickness

TABLE 21-7 Risk Factors Associated with Sudden Cardiac Death in Hypertrophic Cardiomyopathy

Major risk factors
Prior cardiac arrest
Spontaneous sustained ventricular tachycardia
Positive family history of premature death
Multiple syncopal or near-syncopal episodes, especially if associated with exertion
Multiple and repetitive or prolonged episodes of nonsustained ventricular tachycardia
Marked left ventricular hypertrophy ≥30 mm
Hypotensive blood pressure response to exercise
Potential individual risk factors
Atrial fibrillation
Myocardial ischemia
Left ventricular outflow obstruction
Identification of a malignant genotype
Intense (competitive) physical exertion

>30 mm) are at high risk for sudden death even if they are asymptomatic. A high LV outflow tract pressure gradient ≥30 mm Hg is a strong predictor for older patients.[64] Presentation of HCM in the later decades of life is common. Patients who present with HCM at an advanced age of 65 years or older usually have a prognosis that is no different from that of age- and gender-matched controls. Elderly patients with HCM tend to have mild degrees of LVH, and their symptoms are not severe.[65] Because systolic hypertension and diastolic HF are common in the elderly, the diagnosis of HCM may be challenging. However, marked LVH out of proportion to blood pressure, unusual patterns of LVH, or an outflow obstruction at rest strongly suggests HCM.[55]

TREATMENT

Hypertrophic Cardiomyopathy

DESIRED OUTCOMES

Because no known means are available for preventing HCM, the focus must be on methods to minimize the consequences of the disorder.

GENERAL APPROACH TO TREATMENT

8 The treatment of HCM is designed to reduce symptoms, improve exercise tolerance, retard disease progression, and improve prognosis. Agents that decrease contractility, improve diastolic dysfunction, reduce ischemia, and suppress arrhythmias have been used with some success (Fig. 21–2). In 2003, the ACC in conjunction with the ESC published a consensus document on HCM.[66]

NONPHARMACOLOGIC THERAPY

In the past, surgical treatment was reserved for patients who were refractory to medical management and had an outflow gradient ≥50 mm Hg, a very thick ventricular septum, and high LV pressures. Surgical intervention relieves the outflow obstruction and the elevated LV pressures. The surgeon accomplishes this by performing a myectomy (i.e., removal of excess tissue). The procedure results in a reduction in LV filling pressures and a long-term improvement in symptoms. Myectomy has demonstrated a long-term survival benefit in severely symptomatic patients with obstruction by altering the course of the disease.[60]

Ablation of the myocardium using alcohol is an alternative to surgery. Septal ablation with alcohol results in the same type of outcomes as seen with myectomy. Long-term follow-up is limited because this procedure has been used for less than a decade. Because it is a percutaneous procedure (similar to cardiac catheterizations), it is being performed more frequently than myectomy. There is some concern that the risk for arrhythmia-related cardiac events may increase following alcohol ablation. Long-term follow-up is needed to assess this risk. Complete heart block is a common complication of septal ablation (14% in one case series) and requires a permanent pacemaker if it occurs.[58,60]

The results of uncontrolled studies suggested that dual-chamber pacing decreased LV outflow gradients and improved symptoms.

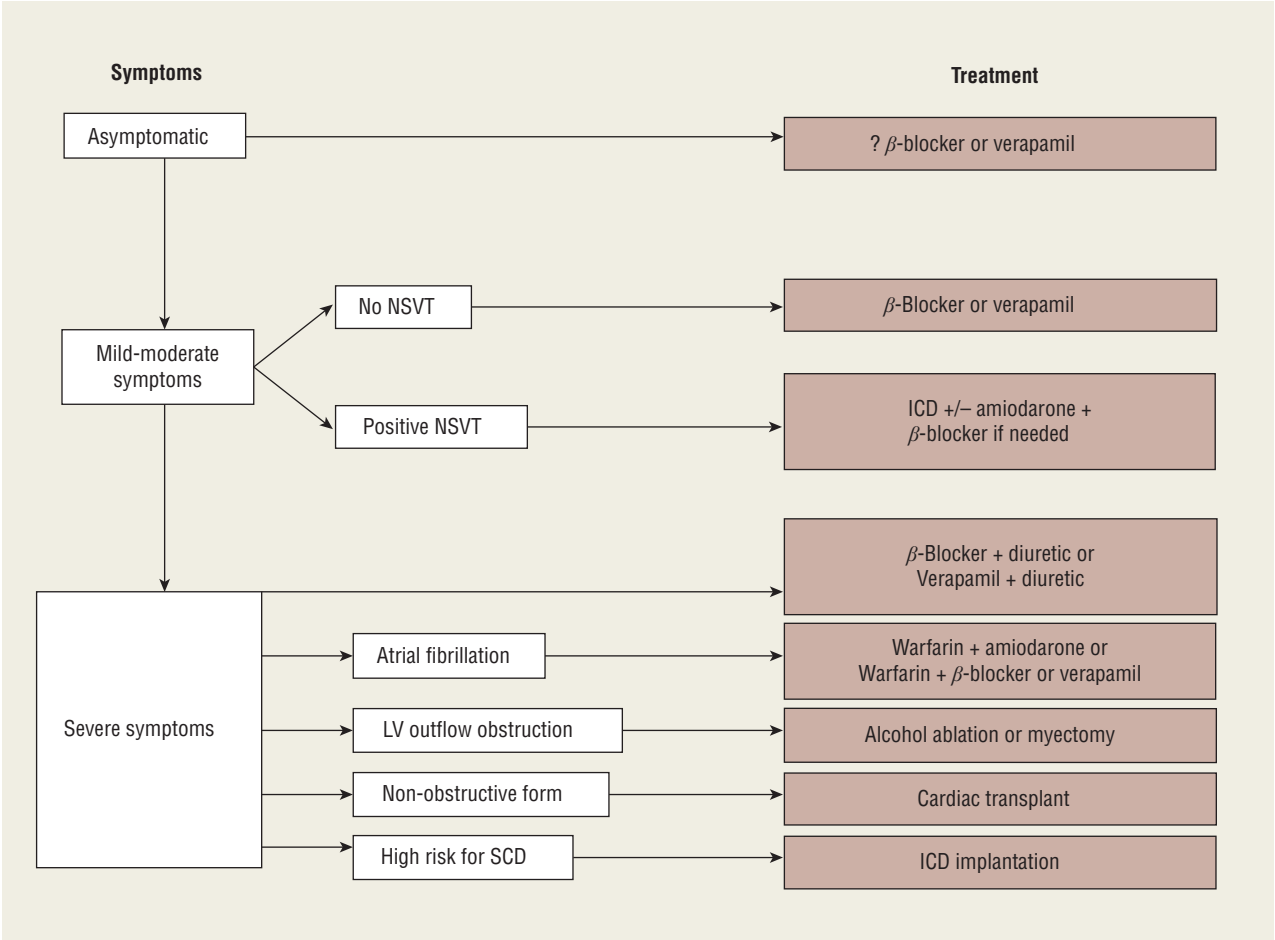

FIGURE 21-2. Treatment algorithm for hypertrophic cardiomyopathy (ICD = implantable cardioverter-defibrillator; LV = left ventricular; NSVT = nonsustained ventricular tachycardia; SCD = sudden cardiac death; ? = questionable role).

Subsequent controlled trials were not able to replicate the initial findings and demonstrated more modest improvement. Consequently, the ACC/AHA/HRS issued guidelines suggesting pacing for severely symptomatic patients who have not responded to medical management (class IIb recommendation, or one in which the efficacy is less well established by evidence).[67] The Canadian Cardiovascular Society recommends following the guidelines for LV systolic dysfunction regarding dual chamber pacing.[57]

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

9 Sudden death is the most worrisome outcome of HCM, and the implantable cardioverter-defibrillator (ICD) is the most effective therapy for prevention of sudden death. It is difficult to know when to implant an ICD, especially in a young patient diagnosed with HCM. Patients who are candidates for an ICD for primary prevention will be young and relatively asymptomatic. In 2006, the ACC/AHA with the ESC published updated guidelines designating the ICD for prevention of sudden death (class IIa recommendation or one in which the weight of the evidence or opinion favors efficacy). These guidelines stipulate that patients should exhibit one or more major risk factors for sudden death (see Table 21–7), are currently be receiving chronic medical therapy, and have a reasonable survival with good functional status at 1 year. For secondary prevention following cardiac arrest, ICD placement is considered a class I recommendation, where there is evidence or general agreement that the procedure is beneficial.[68] Conducting a clinical trial to provide evidence for a higher-level recommendation for primary prevention is unlikely to occur.

PHARMACOLOGIC THERAPY

Beta-Adrenergic Blockers

10 Beta-blocking agents have been used in obstructive and nonobstructive forms of HCM since the 1960s and are recommended as first-line drug therapy to control symptoms.[57] Doses up to 480 mg/day of propranolol or its equivalent are used. Resting heart rate should be 60 beats/min, and the maximum exercise heart rate should be <120 beats/min. The mechanism by which β-blockade is beneficial is by inhibiting sympathetic stimulation of the heart. Myocardial oxygen demand is reduced by decreasing heart rate, LV contractility, and myocardial wall stress during systole. Outflow tract obstruction may be minimized with β-blockade, especially under conditions of stress or exercise, when sympathetic stimulation is high.

Calcium Channel Blockers

Patients who have an inadequate response to β-blockade may respond to verapamil.[56] Doses of verapamil up to 480 mg/day have beneficial effects on symptoms.[66] Calcium channel blockers may be of benefit to patients with HCM for several reasons. Increased calcium concentrations have been shown to play a role in prolonging ventricular depolarization, as well as the duration of isometric contraction and relaxation. Patients with HCM have a hyperdynamic ventricle in systole and delayed relaxation and decreased compliance during diastole. Calcium channel blockers decrease the myocardial oxygen demand, resulting in an improved balance between oxygen supply and demand; therefore, diastolic function may be improved.

Most patients with HCM who have been treated with a calcium channel blocker have received verapamil, although others also have been used. IV verapamil has been noted to acutely reduce the outflow tract gradient in patients with obstructive HCM. The mechanism may be a decrease in systolic function as well as an increase in LV volumes as a result of enhanced LV diastolic filling.

The adverse effects associated with use of verapamil include constipation, sinus nodal blockade, prolongation of the PR interval, AV dissociation, hypotension, and pulmonary congestion. The risks may outweigh the benefits in patients with (a) a markedly elevated pulmonary capillary wedge pressure or pulmonary artery occlusion pressure, (b) a history of paroxysmal nocturnal dyspnea or orthopnea, (c) sick sinus syndrome or significant AV nodal disease in the absence of a permanent pacemaker, (d) low systolic blood pressure, and (e) a substantial outflow gradient. Verapamil should be avoided in patients with HF as a result of systolic dysfunction.[66] There is no evidence that either β-blockade or verapamil protects the patient from sudden cardiac death.

Studies using other calcium channel blockers are limited. Improvement in diastolic dysfunction may occur, but the dihydropyridines may cause a reflex increase in heart rate or hypotension or worsen the outflow tract gradient.

Antiarrhythmic Agents

Disopyramide has been used for treating both the supraventricular and ventricular arrhythmias occurring in patients with HCM. In addition, the negative inotropic effect and the ability to increase peripheral vascular resistance attributed to disopyramide have been used to reduce outflow tract obstruction. The anticholinergic side effects (blurred vision, dry mouth, and urinary retention) make disopyramide a problematic agent for long-term therapy in some patients. The QT interval on the ECG should be monitored in patients on disopyramide.[66]

The role of amiodarone for the prevention of sudden death in patients with HCM has been questionable. A few nonrandomized studies have suggested a protective effect, whereas others demonstrate only symptomatic improvement. Nonetheless, the 2006 ACC/AHA/ESC guidelines give amiodarone a class IIb recommendation for primary prophylaxis against sudden death in patients with HCM when ICD placement is not feasible and who demonstrate one or more major risk factors for sudden death (see Table 21–7). Furthermore, in patients with HCM who are not candidates for ICD placement and have suffered a cardiac arrest, amiodarone therapy is considered the preferred treatment (class I recommendation).[68]

A significant number of patients with HCM develop atrial fibrillation. Amiodarone is one of the most effective agents available to maintain normal sinus rhythm in these patients. For patients in chronic atrial fibrillation requiring rate control, a β-blocker or verapamil may be used. Anticoagulation should be considered because these patients are at risk for systemic embolization and stroke. If amiodarone is added to the therapy of a patient already receiving warfarin, the prothrombin time or international normalized ratio will be increased and should be monitored closely.[56]

Other Drugs

There is a small risk for bacterial endocarditis in patients with LV outflow obstruction under resting conditions and in those with intrinsic mitral valve disease. Patients undergoing dental or selected surgical procedures that cause bloodborne bacteremia should receive appropriate antibiotic therapy. The administration of nitroglycerin and digoxin generally is discouraged in the presence of LV outflow obstruction.[66]

CLINICAL CONTROVERSY

Some clinicians believe that ACE inhibitors have no role in the management of HCM with LV outflow obstruction. Others believe that ACE inhibitors may be beneficial by limiting hypertrophy.

Evaluation of Therapeutic Outcomes

The goal of treatment of patients with HCM is primarily to reduce their symptoms of dyspnea and exercise intolerance. Either β-blocker or calcium channel blockers can be used. If a β-blocker is chosen, it is best to use an agent that does not have intrinsic sympathomimetic activity. The dose should be maximized. If the patient does not tolerate a β-blocker or has a contraindication to use of a β-blocker, then verapamil can be tried. Patients should be monitored for resolution of symptoms and an increase in exercise tolerance. Resolution of symptoms may take months to occur. In addition, both β-blockers and calcium channel blockers may cause hypotension and conduction abnormalities. Beta-blockers may worsen pulmonary function. If dyspnea continues with maximal doses of a β-blocker or calcium channel blocker, a diuretic agent or a nitrate may be added with caution. Patients who are at high risk for sudden cardiac death should be considered candidates for an ICD.

For patients with significant obstruction to LV outflow who do not respond to medical management, a surgical approach may be necessary. Septal myectomy and alcohol ablation have been used. These approaches generally are reserved for patients who have an exercise outflow gradient >50 mm Hg or resting outflow gradient >30 mm Hg and/or severe symptoms and who have not responded to an adequate trial of medical therapy.

RESTRICTIVE CARDIOMYOPATHY

Restrictive cardiomyopathy is primarily an abnormality of diastolic function that results in impaired filling and increases in ventricular end-diastolic pressures with normal or decreased diastolic volume. It is associated with normal systolic function early in the course of the disease but a decrease in systolic function later in the disease process. Either one or both of the ventricles may be affected; therefore, restrictive cardiomyopathy may present as either left- or right-sided HF.[55]

Epidemiology and Etiology

Restrictive cardiomyopathy is encountered less frequently in Western countries. Because restrictive cardiomyopathy is rare, the natural course of the disease is not well characterized, and reports on prognosis have been highly variable. Restrictive cardiomyopathies may be classified as either myocardial or endomyocardial. The myocardial types may be noninfiltrative, infiltrative, or storage diseases. The endomyocardial types are due to endomyocardial fibrosis, hypereosinophilic syndrome, carcinoid heart disease, metastatic cancers, radiation, and anthracycline toxicity or secondary to drugs known to cause fibrosis.[57]

Restrictive myocardial disease may result from several local or systemic disorders. Amyloidosis, hemochromatosis, scleroderma, carcinoid, sarcoidosis, diabetes, pseudoxanthoma elasticum, and endomyocardial fibrosis have been known to cause restrictive cardiomyopathy. The most common cause of restrictive cardiomyopathy in the industrialized world is amyloidosis, whereas endomyocardial fibrosis is a common cause in tropical areas of the world. There may be a genetic predisposition to idiopathic restrictive cardiomyopathy.[57]

Pathophysiology

The major hemodynamic abnormality in restrictive cardiomyopathy is a limitation in ventricular filling leading to reduced diastolic volumes of one or both ventricles.[57] The cavity size and wall thickness of the ventricles usually are normal. Atrial dimensions often are increased. Thrombi are found frequently in the cardiac chambers. Patients may have signs and symptoms consistent with HF. The abnormality is similar to that seen in pericardial disease causing constriction or tamponade.

Diagnosis

The diagnosis of restrictive cardiomyopathy should be considered in any patient who presents with signs and symptoms of HF but has only mild cardiomegaly. A positive Kussmaul sign is common when symptoms of HF are present.[57] Differentiation from constrictive pericarditis is important because pericardectomy is an effective form of treatment of constrictive pericarditis. Recent studies have focused on using BNP as a potential noninvasive marker for differentiation of the two conditions.[69] Other laboratory tests or endomyocardial biopsy can be performed to look for diseases such as amyloidosis and hemachromatosis.

TREATMENT

Restrictive Cardiomyopathy

The treatment of restrictive cardiomyopathy is complex because of the heterogeneity of the pathophysiologic abnormalities.[57] Diuretics are used for the symptoms of venous congestion in the presence of restrictive cardiomyopathy, but caution is advised because these patients require high filling pressures to maintain an adequate stroke volume and cardiac output. Hypotension and hypoperfusion may occur as a result of excessive use of diuretics. Because systolic function often is normal, digoxin is of little benefit and may be proarrhythmic. Amiodarone can be used to maintain normal sinus rhythm in patients who have episodes of atrial fibrillation. Anticoagulation is needed to decrease the risk of systemic embolization, particularly in patients with atrial fibrillation, valvular regurgitation, and low cardiac output. In the case of hemochromatosis, chelation therapy and/or repeated phlebotomy may be of benefit. Treatment with corticosteroids and cytotoxic drugs has been used with some success in the early phase of endomyocardial fibrosis and eosinophilic cardiomyopathy.

Evaluation of Therapeutic Outcomes

The first step in assessing and treating a patient with restrictive cardiomyopathy is to rule out constrictive pericarditis because the two conditions have a similar presentation. Patients with constrictive pericarditis are treated easily with surgery, whereas patients with restrictive cardiomyopathy undergo a varied approach to therapy depending on the etiology of their disorder. The treatment is aimed at relieving the symptoms associated with high filling pressures. This is achieved generally through the use of diuretics. Diuretic therapy should be initiated with low doses. Normalization of filling pressures is not possible or desirable. Patients' symptoms should be monitored for improvement. Excessive diuresis will result in inadequate cardiac output. Chelation therapy has been advocated for patients with hemochromatosis. Prednisone has been suggested for patients with sarcoidosis. There is no curative treatment for restrictive cardiomyopathy.

OTHER CARDIOMYOPATHIES

Tachycardia-induced cardiomyopathy (TIC) is a reversible form of HF. The incidence of TIC is unknown but generally thought to be uncommon. It is associated with persistent supraventricular or ventricular arrhythmias and may occur in patients of all ages.[57,70] With prolonged tachycardia, the heart dilates, LVEF decreases, but hypertrophy does not occur. Recovery of EF and resolution of symptoms may occur within 1 month after treatment. However, if tachycardia recurs, a precipitous decline in EF may occur, along with possible sudden cardiac death.[70] The sinus node inhibitor ivabradine has been reported to improve symptoms and systolic function and may warrant further evaluation.[71]

There are also a number of endocrine disorders associated with cardiomyopathy, including acromegaly, adrenal insufficiency, Cushing disease, hyperthyroidism, myxedema, and pheochromocytoma.[57] Treatment is targeted at the underlying endocrine disease.

When patients present with dilated cardiomyopathy, alcohol consumption should be investigated. Alcohol consumption is associated with myocardial fibrosis, impaired sarcoplasmic reticulum uptake of calcium, inhibition of myosin ATPase, and diastolic dysfunction. Generally, excessive alcohol intake for a prolonged period (10 or more years) is likely to occur before symptoms develop. Treatment is abstinence from alcohol.[57] Patients receiving other known cardiotoxic agents, such as anthracyclines, should follow established dosing guidelines and be monitored closely. Chronic cocaine use can cause cardiomyopathy through direct toxicity to the myocardium as well as promoting atherosclerosis- and vasospasm-induced ischemia. As with alcohol, abstinence is critical for patients with cocaine-induced cardiomyopathy. Standard HF therapies should be initiated; however, use of β-blockers is discouraged if the patient is likely to continue the use of cocaine.[72]

CHAPTER 22

Acute Decompensated Heart Failure

JO E. RODGERS AND CRAIG R. LEE

KEY CONCEPTS

1. Unlike chronic heart failure therapies whose primary benefit is an improvement in survival, treatment goals of acute decompensated heart failure (ADHF) are directed toward relief of symptoms of pulmonary edema, restoration of systemic oxygen transport and tissue perfusion, and limitation of further cardiac damage and other adverse effects.
2. Maximizing oral chronic heart failure therapy and using combinations of short-acting intravenous medications with different cardiovascular actions are often needed to optimize cardiac output, relieve pulmonary edema, and limit myocardial ischemia.
3. Patients presenting to the hospital with ADHF can be categorized into four subsets based upon fluid status (euvolemic or "dry" vs fluid overload or "wet") and cardiac output (adequate cardiac output or "warm" vs hypoperfusion or "cold"). Thus, patients are warm and dry, warm and wet, cold and dry, or cold and wet.
4. While invasive hemodynamic monitoring using a pulmonary artery or Swan Ganz catheter has been shown to not alter outcomes in a broad population of ADHF patients not requiring such monitoring, it is indicated for patients who are refractory to initial therapy, whose volume status is unclear, or who have clinically significant hypotension such as a systolic blood pressure less than 80 mm Hg or worsening renal function despite therapy. In addition, pulmonary artery catheter monitoring may also be necessary to provide immediate feedback on treatment efficacy and adverse effects.
5. Key hemodynamic parameters to assess with pulmonary artery catheter monitoring include pulmonary capillary wedge pressure, which reflects fluid status or preload; cardiac output, which reflects the innate contractility of the heart; and systemic vascular resistance, which reflects vascular tone or afterload. While a normal pulmonary capillary wedge pressure (6 to 12 mm Hg) is desirable in most healthy patients, higher filling pressures (15 to 18 mm Hg) are necessary in patients with heart failure.
6. Three major therapeutic categories exist for managing ADHF: diuretics, inotropes, and vasodilators. No therapy for ADHF studied to date has been shown conclusively to decrease mortality. Inotropic therapy consistently has been associated with increased mortality and adverse effects in multiple studies.
7. Intravenous loop diuretics are considered first-line therapy for management of ADHF associated with fluid overload. A variety of therapeutic options are recommended for managing refractory fluid overload, including increasing loop diuretic intravenous bolus dose, adding a diuretic with a different mechanism of action, and transitioning to a continuous infusion of loop diuretic. Ultrafiltration is also an option for patients refractory to diuretics. If patients continue to be refractory to and experience worsening renal function with diuretic therapy, vasodilator and inotropic therapy may be indicated. Placement of a pulmonary artery catheter may be helpful in guiding therapy in such patients.
8. Intravenous inotropes are recommended for symptom relief or end-organ dysfunction for patients with left ventricular dysfunction and low cardiac output syndrome. Such therapy may be especially useful for patients with low systolic blood pressure (less than 90 mm Hg) or symptomatic hypotension in the setting of adequate filling pressures. Inotropic therapy may also be considered for patients who do not tolerate or respond to intravenous vasodilators or who present worsening renal function. These agents should be avoided in patients with reduced left heart filling pressures, and patients should be monitored continuously for arrhythmias.
9. Given the potential risks associated with inotropic therapy, vasodilators should be considered prior to using inotropes.
10. Intravenous vasodilators may be considered in addition to diuretics for rapid symptom resolution and may be especially useful for patients with acute pulmonary edema or severe hypertension as well as for patients who fail to respond to aggressive treatment with diuretics. It is essential to avoid use of vasodilators for patients with symptomatic hypotension, and frequent blood pressure monitoring is essential for the safe use of these agents. In addition, these agents should not be used for patients with reduced left heart filling pressures. If patients fail to respond to the above therapies or experience worsening renal function, intravenous inotropic therapy should be considered.
11. Vasopressin antagonists provide a new therapeutic option for managing hyponatremia in patients with euvolemic or hypervolemic hyponatremia. Tolvaptan is the only vasopressin antagonist indicated for managing hyponatremia associated with heart failure. Despite tolvaptan being an oral agent, it should only be initiated in the hospital setting to allow for

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

close monitoring of rapidity of serum sodium correction and volume status. Over-rapid correction of serum sodium may result in adverse neurological sequelae.

12 Given extended wait times for patients on the cardiac transplant list, insertion of a ventricular assist device may be considered for patients in whom extended time to identify a suitable donor is likely to occur (i.e., "bridge" to transplant) or in whom transplantation is not an option (i.e., "destination" therapy).

As discussed in Chap. 20 (Systolic Heart Failure), the number of patients with heart failure is substantial and continues to increase. Although survival from heart failure, has improved, the growing number of patients with the disorder and the progressive nature of the syndrome have lead to substantial increases in hospitalizations for heart failure.[1] Recent data indicate approximately 1 million patients are hospitalized annually for heart failure resulting in significant morbidity, mortality, and consumption of large quantities of healthcare resources.[1,2] Inpatient admission for heart failure is associated with an increased risk of subsequent hospitalization and decreased survival.[3] In fact, recent data suggest that the mortality rate following hospitalization for heart failure is 10.4%, 22%, and 42.3% at 30 days, 1 year, and 5 years, respectively. Additional data suggest an in-hospital mortality rate of 5.1%.[2] The economic impact of heart failure is considerable, with cost driven primarily by inpatient care.[1,2]

A number of descriptive terms have been used to characterize patients with worsening heart failure requiring hospitalization. Patients with persistent symptoms or *refractory* heart failure requiring specialized interventions despite optimal standard therapy such as angiotensin-converting enzyme (ACE) inhibitors and β-blockers are classified as stage D in the American College of Cardiology/American Heart Association (ACC/AHA) classification scheme.[4,5] These patients typically fall into the category of New York Heart Association (NYHA) class III or IV heart failure with symptoms upon minimal exertion or at rest. The terms *decompensated heart failure* or *exacerbation of heart failure* refer to those patients with new or worsening signs or symptoms that are usually caused by volume overload and/or hypoperfusion and lead to additional medical care such as emergency room visits and hospitalizations. The term *acute* heart failure may be misleading as it more often refers to the patient with a sudden onset of signs or symptoms of heart failure in the setting of previously normal cardiac function. This chapter will focus on the management of patients with acute decompensated heart failure (ADHF). Clinical syndromes within decompensated heart failure include pulmonary or systemic volume overload, low cardiac output, and acute pulmonary edema. It is important to recognize that such patients may present with impaired (left ventricular ejection fraction less than 40%) or preserved (left ventricular ejection fraction greater than or equal to 40%) left ventricular systolic function and a variety of etiologies may be responsible for the primary disease process. The clinical course of heart failure manifests as periods of relative stability with an increasing frequency in episodes of decompensation as the underlying disease progresses.[6]

Despite the considerable morbidity and mortality associated with decompensated heart failure, the first randomized placebo-controlled trials in this patient population were published in 2002.[7,8] In addition, it was not until 2005 that guidelines specifically focused on managing decompensated heart failure were generated. The Heart Failure Society of America (HFSA) and the European Society of Cardiology have published separate guidelines for evaluating and treating decompensated heart failure.[9,10] The 2005 ACC/AHA guidelines had previously focused a portion of their recommendations for chronic heart failure on the decompensated patient.[4] However, the 2009 update has also provided specific recommendations for the hospitalized patient.[5] Since available drug therapies differ between Europe and the United States, the HFSA and ACC/AHA guidelines will be the focus of the remainder of this chapter.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Patients requiring intensive therapy for decompensated heart failure may have a variety of underlying etiologies and clinical presentations.[5,9] Patients with worsening chronic heart failure comprise approximately 70% of heart failure hospital admissions. These patients can become refractory to available oral therapy and decompensate following a relatively mild insult (e.g., dietary indiscretion, nonsteroidal antiinflammatory drug use), cardiac medication noncompliance, or a noncardiac concurrent illness (e.g., infection). A new cardiac event, such as recurrent myocardial infarction, atrial fibrillation, hypertensive urgency/emergency, myocarditis, or acute valvular insufficiency also can cause a stable patient to decompensate. Secondly, de novo heart failure may occur following a large myocardial infarction or sudden increase in blood pressure in the setting of left ventricular dysfunction and represents approximately 25% of admissions. A third group of patients with severe left ventricular systolic dysfunction associated with progressive worsening of cardiac output and refractoriness to therapy represents about 5% of heart failure admissions.[11] Additional insight into the clinical characteristics of decompensated heart failure patients unexpectedly indicates that a high percentage of patients present with hypertension and preserved left ventricular systolic function.[12]

Several studies have also provided a better understanding of the prognostic factors associated with decompensated heart failure. Data from the Acute Decompensated Heart Failure Registry (ADHERE), a registry of hospitalized patients with a primary diagnosis of decompensated heart failure, found BUN greater than or equal to 43 mg/dL to be the best individual predictor of in-hospital mortality, followed by systolic blood pressure less than 115 mm Hg, and then serum creatinine greater than or equal to 2.75 mg/dL. Using these three parameters, patients were identified as low, intermediate, high, and very high risk with in-hospital mortality of 2%, 6%, 13%, and 20%, respectively.[13] Additional studies have confirmed an increase in in-hospital mortality for patients with low systolic blood pressure and worsening renal function on admission.[14,15] Hyponatremia, elevations in troponin I, ischemic etiology, and poor functional capacity are additional negative prognostic factors.[11] Importantly, patients who survive a hospitalization for ADHF remain at high risk for rehospitalization or death.[5] Data from the Organized Program to Initiate Lifesaving Treatment in Hospitalized Patients with Heart Failure (OPTIMIZE-HF), another registry of hospitalized patients with a primary diagnosis of ADHF, have reported overall mortality and rehospitalization rates of 8.6% and 29.6%, respectively, 60 to 90 days postdischarge.[16] Similarly, low blood pressure and poor renal function are negative prognostic factors.[16] However, use of a β-blocker, ACE inhibitor, angiotensin receptor blocker, or lipid-lowering therapy at discharge, and coronary angiography or implantable cardioverter–defibrillator placement during hospitalization were associated with improved prognosis,[16] suggesting that optimal management of these patients in the hospital can yield beneficial effects on prognosis.

GENERAL APPROACH TO TREATMENT

1 2 The overall goals of therapy for the patient with decompensated heart failure are to relieve congestive symptoms or optimize volume status, as well as treat symptoms of low cardiac output, so

that the patient can be discharged in a compensated state on oral drug therapy. Although diuretic, vasodilator, and positive inotrope therapy can be very effective at achieving these goals, their efficacy must be balanced against the potential for serious toxicity. Thus, another important goal is to minimize the risks of pharmacologic therapy. Maintenance of vital organ perfusion to preserve renal function and prevention of additional myocardial injury, diuretic-induced electrolyte depletion, hypotension from vasodilators, and myocardial ischemia and arrhythmias from positive inotropes are all important goals.

In addition, all patients should be evaluated for potential etiologies and precipitating factors, including atrial fibrillation and other arrhythmias, worsening hypertension, myocardial ischemia or infarction, anemia, hypothyroidism or hyperthyroidism, or other causes. Medications, including noncardiac medications, which may worsen cardiac function, should also be considered as precipitating or contributing factors. Patients who may benefit from revascularization should also be identified. Prior to discharge, optimization of chronic oral therapy and patient education are critical to preventing future hospitalizations. When available and appropriate, patients should be referred to a heart failure disease management program.[9] A careful history and physical examination are key components in the diagnosis of decompensated heart failure. The history should focus on the potential etiologies of heart failure; the presence of any precipitating factors, onset, duration, and severity of symptoms; and a careful medication history. Current guidelines recommend making the diagnosis of decompensated heart failure based primarily on signs and symptoms.[9] With congestion representing the more common presentation of heart failure, orthopnea is the main symptom of fluid overload that best correlates with elevated pulmonary pressures.[15] Important elements of the physical examination include assessment of vital signs and weight, cardiac auscultation for heart sounds and murmurs, pulmonary exam for the presence of rales, and evaluation for the presence of peripheral edema. The jugular venous pressure is the most reliable indicator of the patient's volume status and should be carefully evaluated on admission and closely followed during hospitalization as an indicator of the efficacy of diuretic therapy.[15] An S3 gallop also represents ventricular filling and has high diagnostic specificity for heart failure decompensation. Other physical findings such as pulmonary crackles and lower extremity edema have low specificity and sensitivity for the diagnosis of decompensated heart failure.[9] The development of a bedside assay for plasma b-type natriuretic peptide (BNP) has focused considerable attention on the use of natriuretic peptide levels as an aid in the diagnosis of suspected heart failure.[17] Plasma BNP and N-terminal pro-BNP levels are positively correlated with the degree of left ventricular dysfunction and heart failure, and these assays are now frequently used in acute care settings to assist in the differential diagnosis of dyspnea (heart failure vs asthma, COPD, or infection). A low BNP concentration has a 96% predictive value for excluding heart failure as an etiology when evaluating patients presenting with dyspnea. In addition, an elevated pre-hospital discharge BNP concentration is associated with an increased risk of worse long-term outcome. It is important to note that any disease process that increases right heart pressures will elevate BNP, including pulmonary emboli, chronic obstructive lung disease, and primary pulmonary hypertension. Also, BNP levels may be mildly increased with increasing age, female gender, and renal dysfunction while concentrations may be lower with obesity.[15] Additional research will better characterize the role of BNP measurement in the diagnosis and treatment of heart failure. When the diagnosis of decompensated heart failure is uncertain, current guidelines recommend obtaining a BNP concentration in conjunction with assessing signs and symptoms.[5,9]

TABLE 22-1 Recommendations for Hospitalizing Patients Presenting with ADHF

Recommendation	Clinical Circumstances
Hospitalization recommended	Evidence of severely decompensated HF, including • Hypotension • Worsening renal function • Altered mentation Dyspnea at rest • Typically reflected by resting tachypnea • Less commonly reflected by oxygen saturation <90% Hemodynamically significant arrhythmia • Including new onset of rapid atrial fibrillation Acute coronary syndromes
Hospitalization should be considered	Worsened congestion • Even without dyspnea • Typically reflected by a weight gain of ≥5 kg Signs and symptoms of pulmonary or systemic congestion • Even in the absence of weight gain Major electrolyte disturbance Associated comorbid conditions • Pneumonia • Pulmonary embolus • Diabetic ketoacidosis • Symptoms suggestive of transient ischemic accident or stroke Repeated implantable cardioverter-defibrillator firings Previously undiagnosed HF with signs and symptoms of systemic or pulmonary congestion

Data from Adams KF, Lindenfeld J, Arnold JMO, et al. HFSA 2006 Comprehensive Heart Failure Practice Guidelines. J Cardiac Fail 2006;12:e1–e122.

Hospitalization *is recommended* or *should be considered*, depending on each patient's presenting symptoms and physical exam. Table 22–1 describes the clinical presentation of patients in whom hospitalization should occur or should be considered. Most patients do not require admission to an intensive care unit and are admitted to a monitored unit or general medical floor. Admission to an intensive care unit may be required if the patient experiences hemodynamic instability requiring frequent monitoring of vital signs, invasive hemodynamic monitoring, or rapid titration of intravenous medications with concurrent monitoring to assure safe and effective outcomes.

The first step in the management of decompensated heart failure is to ascertain that optimal treatment with oral medications has been achieved.[5,9] If fluid retention is evident on physical examination, aggressive diuresis should be accomplished. Although increasing the dose of oral diuretic may be effective in some cases, the use of intravenous diuretics frequently is necessary. Every effort should be made to optimally treat the patient with an ACE inhibitor. β-blocker therapy should generally be continued during the hospital admission unless recent dose initiation or uptitration was responsible for the decompensated state. In such cases, β-blocker therapy may need to be temporarily held or dose reduced. Appropriateness of initiating this therapy prior to hospital discharge will be discussed later in this chapter. Discontinuation of ACE inhibitor or β-blocker therapy occasionally may be necessary in the setting of cardiogenic shock or symptomatic hypotension. Certain therapies may also need to be temporarily held in the setting of renal dysfunction especially in the setting of oliguria or hyperkalemia (e.g., ACE inhibitor, angiotensin receptor blocker, and/or aldosterone antagonist) or elevated serum digoxin concentrations. Most patients should be receiving digoxin at a low dose prescribed to achieve a trough serum concentration of 0.5 to 1.0 ng/mL.[18]

There are two general approaches to maximize therapy in the decompensated heart failure patient. One is to use simple clinical

TABLE 22-2 Monitoring Recommendations for Patients Hospitalized with ADHF

Value	Frequency	Specifics
Weight	At least daily	Determine after voiding in the morning Account for possible increased food intake due to improved appetite
Fluid intake/output	At least daily	Strict documentation necessary
Vital signs	More than daily	Including orthostatic blood pressure
Signs	At least daily	Edema, ascites, pulmonary rales, hepatomegaly, increased jugular venous pressure, hepatojugular reflux, liver tenderness
Symptoms	At least daily	Orthopnea, paroxysmal nocturnal dyspnea, nocturnal cough, dyspnea, fatigue
Electrolytes	At least daily	Potassium, magnesium, sodium
Renal function	At least daily	blood urea nitrogen, serum creatinine

Data from Adams KF, Lindenfeld J, Arnold JMO, et al. HFSA 2006 Comprehensive Heart Failure Practice Guidelines. J Cardiac Fail 2006;12:e1–e122.

parameters (e.g., signs and symptoms, blood pressure, renal function), and the other is to use invasive hemodynamic monitoring in addition to these clinical parameters. In all decompensated heart failure patients, close monitoring is essential for assuring optimal response to therapy while avoiding adverse effects. Daily monitoring should include weight, strict fluid intake and output, and heart failure signs and symptoms to assess clinical efficacy of drug therapy. Foley catheter placement is not recommended unless close monitoring of urine output is needed. As safety end points, monitoring for electrolyte depletion, symptomatic hypotension, and renal dysfunction should be assessed frequently. While many of the above parameters may be monitored daily, some will need to be monitored more frequently as dictated by the patient's clinical status. Vital signs should be assessed multiple times throughout the day at a frequency that is appropriate for a given patient's level of stability. Orthostatic blood pressure should be assessed at least once daily.[9] Recommendations for monitoring are summarized in Table 22–2.

PRINCIPLES OF THERAPY BASED ON CLINICAL PRESENTATION

3 Appropriate medical management of the patient presenting with decompensated heart failure is aided by determination of whether the patient has signs and symptoms of fluid overload ("wet" heart failure) or low cardiac output ("cold" heart failure).[15,19] As previously discussed, most patients present with *fluid overload* (or the "wet" profile). Symptoms consistent with pulmonary congestion include orthopnea and dyspnea with minimal exertion and those of systemic congestion include gastrointestinal discomfort, ascites, and peripheral edema. Patients with no or minimal fluid overload (or the "dry" category of decompensated heart failure) may have symptoms that are more difficult to distinguish. Such patients may present with a syndrome of *low cardiac output* ("cold" heart failure), which is characterized principally by extreme fatigue and tiredness as well as other symptoms not commonly attributed to cardiac causes such as poor appetite, nausea, and early satiety. It is important to recognize that gastrointestinal symptoms may be associated with congestion rather than low cardiac output to the gastrointestinal tract. Moreover, these patients frequently exhibit worsening renal function and a decline in serum sodium level, which, as previously discussed, are each associated with poor prognosis. Many patients will present with signs and symptoms of both wet and cold types of ADHF. In these patients, low-output symptoms may not be obvious until congestion is optimally treated. Figure 22–1 outlines a suggested treatment approach based on whether the patient has signs and symptoms of fluid overload and/or low cardiac output.

PRINCIPLES OF THERAPY BASED ON HEMODYNAMIC SUBSETS

Patients with decompensated heart failure may have critically reduced cardiac output, usually with low arterial blood pressure and systemic hypoperfusion resulting in organ system dysfunction (i.e., cardiogenic shock). They also may have pulmonary edema with hypoxemia, respiratory acidosis, and markedly increased work of breathing. With cardiopulmonary support, response to interventions should be assessed promptly to allow for timely adjustments in treatment. Since cardiopulmonary support must be instituted and adjusted rapidly, immediate assessment of the results of an intervention limits risks and makes adjustments in therapy more prompt. ECG monitoring, continuous pulse oximetry, urine flow monitoring, and automated blood pressure recording are now the minimal noninvasive standard of care for critically ill patients with cardiopulmonary decompensation. Peripheral or femoral arterial catheters may be utilized for continuous and accurate assessment of arterial pressure.

HEMODYNAMIC MONITORING

4 5 The role of invasive hemodynamic monitoring for improving outcomes for patients with decompensated heart failure remains controversial. The Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) trial assessed the role of invasive hemodynamic monitoring in the management of patients hospitalized for heart failure.[20] The use of a pulmonary artery catheter had no impact on survival after hospital discharge. It is important to note that patients with a clear indication for pulmonary artery catheter placement were excluded from this trial. Based upon these study results, the routine use of invasive monitoring is not recommended. However, invasive hemodynamic monitoring often provides essential information to achieve optimal drug therapy for patients with a confusing or complicated clinical picture and during dose titration of rapidly acting medications. Such invasive monitoring should be considered for patients who are refractory to initial therapy, whose volume status is unclear, or who have clinically significant hypotension such as a systolic blood pressure less than 80 mmHg or worsening renal function despite therapy. In addition, documentation of adequate hemodynamic response to inotropic therapy is often necessary prior to committing to chronic outpatient inotropic therapy.[9] Finally, assessment of hemodynamic parameters is required to document adequate reversal of pulmonary hypertension prior to cardiac transplantation.[15]

Invasive hemodynamic monitoring is usually performed with a flow-directed pulmonary artery (PA) or Swan-Ganz catheter placed percutaneously through a central vein and advanced through the right side of the heart and into the PA. Inflation of a balloon proximal to the end port allows the catheter to "wedge," yielding the pulmonary artery occlusion pressure, which estimates the pulmonary venous (left atrial) pressure and, in the absence of intracardiac shunt, mitral valve disease, or pulmonary disease, the left ventricular end diastolic pressure. While the term pulmonary artery occlusion pressure has been utilized in the distant past to describe the filling pressure of the heart, the term *pulmonary capillary wedge pressure* (PCWP) is used more commonly in clinical practice and thus will be used henceforth throughout this chapter. The PCWP is a useful marker of volume status with an elevated

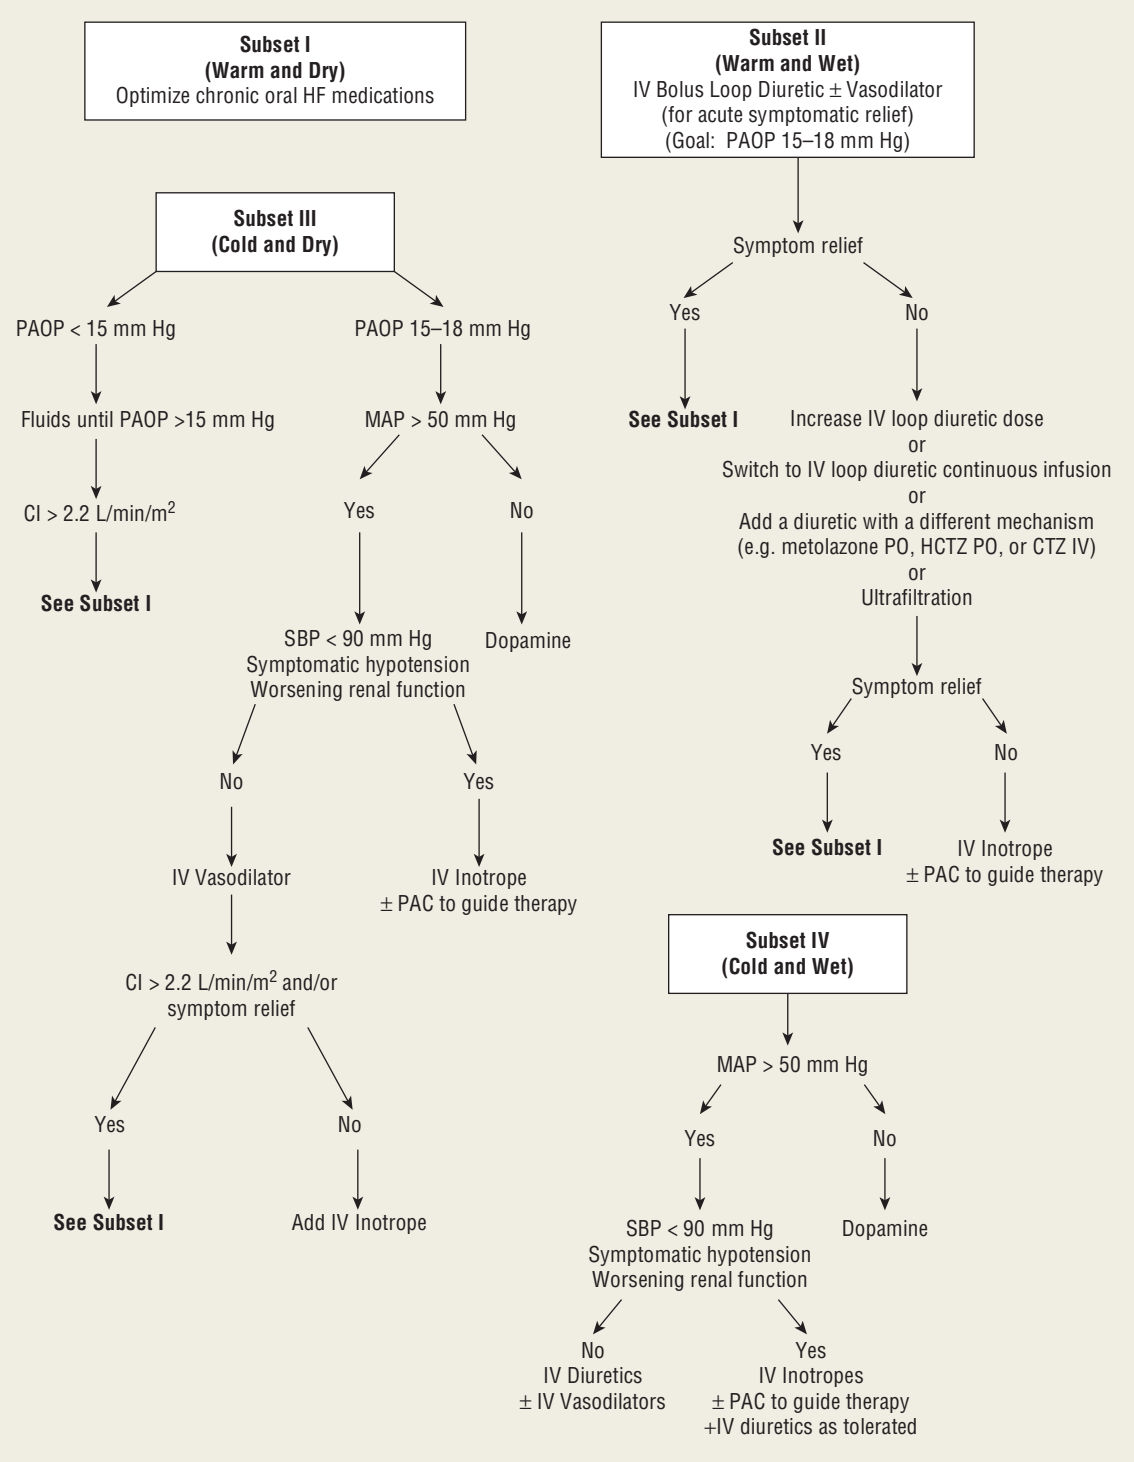

FIGURE 22-1. General treatment algorithm for ADHF based on clinical presentation. IV vasodilators that may be used include nitroglycerin, nesiritide, or nitroprusside. Metolazone or spironolactone may be added if the patient fails to respond to loop diuretics and a second diuretic is required. IV inotropes that may be used include dobutamine or milrinone. *(Reprinted from J Cardiac Fail, Vol 12(1), Heart Failure Society of America, HFSA 2006 Comprehensive Heart Failure Practice Guideline, e120–e122, Copyright © 2006, with permission from Elsevier.)*

PCWP in fluid overload and a reduced PCWP in dehydration. Cardiac output may be measured and represents the volume of blood being pumped by the heart, in particular by the left ventricle, in a minute. Cardiac index (CI) relates the cardiac output to body surface area, thus relating heart performance to the size of the individual. Systemic vascular resistance is calculated using cardiac output and thus is inversely related to cardiac output. Mixed venous oxygen saturation represents the end result of both oxygen delivery and consumption at the tissue level.

The systemic vascular resistance measures the afterload or resistance applied to the left ventricle and is the force impeding the ejection of blood from the left ventricle. The systemic vascular resistance may also be referred to as the *total peripheral resistance*. Vasoconstriction (i.e., decrease in blood vessel diameter) increases vascular resistance, whereas vasodilation (i.e., increase in diameter) decreases resistance. An elevated systemic vascular resistance is common with untreated or decompensated heart failure and is generally responsive to oral or intravenous arterial vasodilators, while reduction in resistance

TABLE 22-3 Hemodynamic Monitoring: Normal Values

Central venous (right atrial) pressure, mean, CVP	<5 mm Hg
Right ventricular pressure (systolic/diastolic)	25/0 mm Hg
Pulmonary artery pressure (systolic/diastolic), PAS/PAD	25/10 mm Hg
Pulmonary arterial pressure, mean, PAP	<18 mm Hg
Pulmonary capillary wedge pressure, mean, PCWP	<12 mm Hg
Systemic arterial pressure (systolic/diastolic), SBP/DBP	120/80 mm Hg
Mean arterial pressure, MAP = DBP + [(1/3)(SBP – DBP)]	90–110 mm Hg
Cardiac output, CO	4–6 L/min
Cardiac index, CI = CO/BSA	2.8–4.2 L/min/m^2
Systemic vascular resistance, SVR = (MAP – CVP) × 80/CO	900–1400 dyne.sec/cm^5
Pulmonary vascular resistance, PVR = (PAP – CVP) × 80/CO	150–250 dyne.sec/cm^5
Arterial oxygen content	20 mL/dL
Mixed venous oxygen content	15 mL/dL

BSA, body surface area

is consistent with sepsis and routinely managed with intravenous vasopressive agents. Arterial vasodilators are the therapy of choice to reduce elevated systemic vascular resistance in heart failure.

While the resistance offered by the peripheral circulation is known as the systemic vascular resistance, the resistance offered by the vasculature of the lungs is known as the *pulmonary vascular resistance*. The pulmonary vascular resistance measures the resistance or impedance of blood flow from the right ventricle against the pulmonary circulation. Pulmonary hypertension and pulmonary edema are two common causes of elevated pulmonary vascular resistance. It is important to recognize that patients with pulmonary hypertension must prove to have reversibility in elevated pulmonary pressures prior to being listed for heart transplant. If not reversible, a patient will likely experience isolated right ventricular failure immediately following heart transplant. Just as systemic resistance is calculated using mean arterial pressure, pulmonary resistance is calculated using mean pulmonary arterial pressure, which is calculated using the pulmonary systolic and pulmonary diastolic pressure. The pulmonary artery diastolic pressure may be useful if the Swan-Ganz catheter fails to wedge, and thus a PCWP is not measurable. If PCWP and pulmonary artery diastolic pressure were determined to correlate prior to failure to wedge, then the pulmonary artery diastolic pressure can be followed as a surrogate marker of fluid status. Normal values for hemodynamic parameters are listed in Table 22–3.

In addition to the clinical presentation, invasive hemodynamic monitoring assists with the classification of patients into specific subsets and the selection of appropriate medical therapy. These *hemodynamic subsets* were first proposed for patients with left ventricular dysfunction following an acute myocardial infarction but also are applicable to patients with acute or severe heart failure from other causes (Fig. 22–2).[21] This hemodynamic classification has four subsets and is based on a CI above or below 2.2 L/min/m^2 and a PCWP above or below 18 mm Hg. A treatment algorithm, based on hemodynamic subsets, is provided in Figure 22–1. In addition to utilizing the above profiles or categories to stratify patients with decompensated heart failure, these four hemodynamic profiles are predictive for outcome with patients in the wet-warm profile having a twofold greater risk of death and those in the wet-cold profile having a 2.5-fold increased risk of death at 1 year compared to dry-warm patients.[15] It is important to note that patients may experience compromised cardiac index in the setting of significant fluid overload and cardiac index may improve as diuresis occurs. The underlying mechanism for how increasing fluid overload further worsens cardiac function is not clearly understood and is depicted in Figure 22–3.

Subset I

Patients in hemodynamic subset I have a CI and PCWP within generally acceptable ranges and have the lowest mortality of any subset.

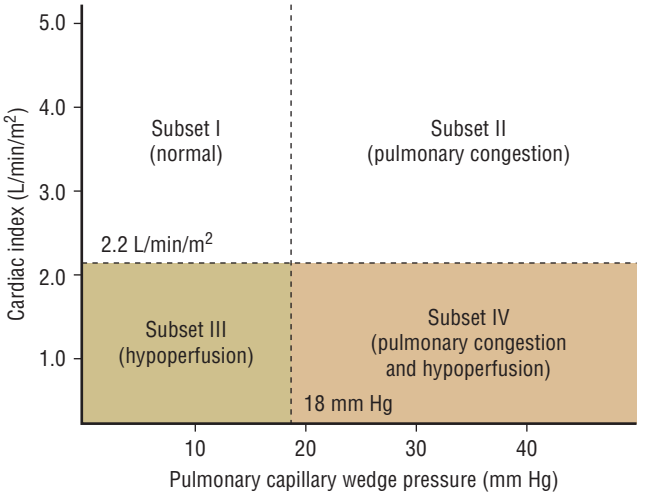

FIGURE 22-2. Hemodynamic subsets of heart failure based on cardiac index and pulmonary artery occlusion pressure. *(Forrester, JS, Diamond G, Chatterjee K, et al. Medical Therapy of Acute Myocardial Infarction by Application of Hemodynamic Subsets. N Engl J Med 1976; 295:1356–1362. Copyright ©1976 Massachusetts Medical Society. All rights reserverd.)*

These patients do not need immediate specific interventions other than maximizing oral therapy and monitoring. It should be emphasized that patients with significant left ventricular dysfunction may still present in subset I because normal compensatory mechanisms and/or appropriate drug therapy may at least partially correct an otherwise abnormal hemodynamic profile.

Subset II

As shown in Figure 22–2, patients in subset II have an adequate CI but a PCWP greater than 18 mm Hg. These patients are likely to have pulmonary congestion (i.e., wet heart failure) secondary to increased hydrostatic pressure in the pulmonary capillaries but no evidence of peripheral hypoperfusion. The primary goal of therapy in these patients is to reduce pulmonary congestion by lowering PCWP, which is associated with improved outcomes. Accordingly, the therapeutic goal in this setting is to reduce filling pressures without reducing cardiac output, increasing heart rate, or further activating neurohormones. Thus, it is critically important that PCWP

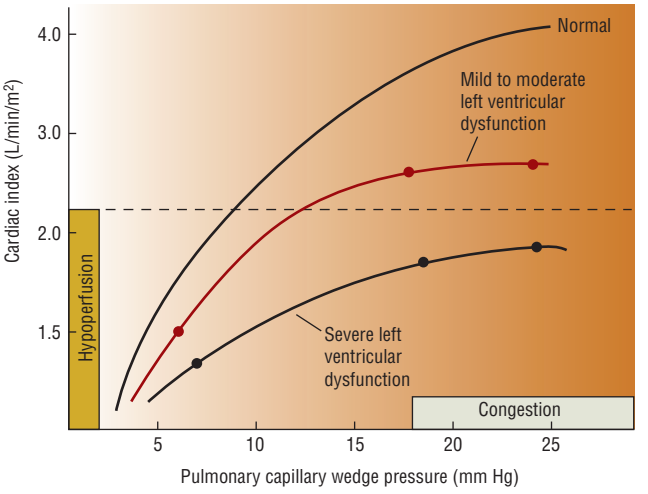

FIGURE 22-3. Relationship between cardiac output (shown as cardiac index, which is CO/BSA) and preload (shown as pulmonary capillary wedge pressure).

not be decreased excessively so as to cause a significant decline in cardiac output. Although the normal range of PCWP is 5 to 12 mm Hg for individuals without cardiac dysfunction, higher pressures of 15 to 18 mm Hg commonly are necessary for heart failure patients to optimize CI. Generally, the PCWP can be lowered to the range of 15 to 18 mm Hg with relatively little decrease in cardiac output because the Frank–Starling curve is flatter at higher PCWP values for patients with heart failure. The Frank–Starling curve in normal and heart failure patients is depicted in Figure 22–3. It is important to note that cardiac output also declines when the PCWP desired in a heart failure patient (i.e., PCWP 15 to 18 mm Hg) is exceeded. This phenomenon may explain why patients may experience enhanced diuresis and improved renal function when the PCWP range of 15 to 18 mm Hg is achieved in a heart failure patient with fluid overload. Intravenous administration of agents that reduce preload (i.e., loop diuretics, nitroglycerin, or nesiritide) are the most appropriate acute therapy to achieve the therapeutic goal for patients in subset II. Despite a very rapid onset with diuretic therapy, the time required for adequate enough diuresis to allow for significant improvement in oxygenation with intravenous loop diuretics may take several hours in select patients. Thus, intravenous nitroglycerin and nesiritide may be utilized for rapid venodilation, which can acutely aid in improving hypoxia.[8]

Current guidelines recommend loop diuretics as first-line therapy for management of heart failure patients admitted with fluid overload and that such agents should typically be administered intravenously.[5,9] The rate of diuresis should achieve a desirable volume status without causing a rapid reduction in intravascular volume resulting in symptomatic hypotension or renal dysfunction. Electrolyte depletion should be monitored for closely, especially when high dose or diuretic combination therapy is utilized. In addition to sodium restriction (less than 2 g daily), supplemental oxygen should be administered as needed for hypoxemia. For patients with moderate hyponatremia (less than 130 mEq/L), fluid restriction (less than 2 L daily) should be considered, and for patients with worsening or severe hyponatremia (less than 125 mEq/L), stricter fluid restriction may be necessary.[5,9] The arginine vasopressin (AVP) antagonists are a new class of agents indicated for the management of euvolemic or hypervolemic hyponatremia in a variety of disease states including heart failure.[22] The currently available vasopressin antagonists are discussed in greater detail later in this chapter.

Intravenous vasodilators may be considered in addition to diuretics for rapid symptom resolution and may be especially useful for patients with acute pulmonary edema or severe hypertension as well as for patients who fail to respond to aggressive treatment with diuretics. It is essential to avoid use of vasodilators for patients with symptomatic hypotension, and frequent blood pressure monitoring is essential for the safe use of these agents. In addition, these agents should not be used for patients with reduced left heart filling pressures. If symptomatic hypotension occurs with vasodilator therapy, the dose should be reduced or the agent discontinued. If patients fail to respond to the above therapies or experience worsening renal function, intravenous inotropic therapy should be considered.[9]

Subset III

Patients in hemodynamic subset III have a CI of less than 2.2 L/min/m^2 but without an abnormally elevated PCWP (Fig. 22–2). These patients usually will present without evidence of pulmonary congestion, but low cardiac output will result in signs and symptoms of peripheral hypoperfusion (i.e., decreased urine output, weakness, peripheral vasoconstriction, weak pulses). The mortality rate of subset III patients is reported to be higher than that of patients without hypoperfusion.[21] Although the treatment goal is to alleviate signs and symptoms of hypoperfusion by increasing CI and perfusion to essential organs, therapy will differ among patients. If the PCWP is significantly below 15 mm Hg, initial therapy will be to administer intravenous fluids to provide a more optimal left ventricular filling pressure of 15 to 18 mm Hg and consequently improve CI. When there is only mild left ventricular dysfunction, intravenous fluid administration may be all that is necessary to achieve a CI above 2.2 L/min/m^2. However, many patients will have significant left ventricular dysfunction and a depressed Frank–Starling relationship despite adequate preload (i.e., PCWP of 15 to 18 mm Hg). In these patients, intravenous administration of positive inotropic agents (e.g., dobutamine, milrinone) and/or arterial vasodilators (e.g., nitroprusside or nitroglycerin) is often necessary to achieve an adequate CI. It is noteworthy that some positive inotropic medications also will have arterial vasodilating activity (see specific drug classes that follow).

Current guidelines recommend intravenous inotropes for symptom relief or end-organ dysfunction for patients with left ventricular dysfunction and low cardiac output syndrome.[5,9] Such therapy may be especially useful for patients with low systolic blood pressure (less than 90 mm Hg) or symptomatic hypotension in the setting of adequate filling pressures. As previously discussed (see Subset II), inotropic therapy may be considered for patients who do not tolerate or respond to intravenous vasodilators or patients with worsening renal function. As with vasodilators, inotrope administration requires frequent blood pressure monitoring as well as continuous monitoring for arrhythmias. If arrhythmias arise, dose reduction or discontinuation of inotropic therapy should occur. As with vasodilators, these agents should be avoided for patients with low left heart filling pressures. Given the potential risks associated with inotropic therapy, vasodilators should be considered prior to using inotropes.[9]

In general, inotropic therapy should not be used widely in the decompensated heart failure population. They are useful to increase cardiac output in the specific patients described above. These agents may be used to "bridge" patients to heart transplantation or left ventricular assist device. Inotropes may also be utilized as palliative therapy to improve functional status and quality of life for patients who are not considered optimal candidates for these definitive therapies.[9]

Subset IV

Patients with a CI of less than 2.2 L/min/m^2 and a PCWP higher than 18 mm Hg are in hemodynamic subset IV. These patients have the worst prognosis of any subset and illustrate the typical hemodynamic profile for the patient hospitalized for end-stage heart failure. Because of severe pump failure, these patients cannot maintain an adequate CI despite the elevated left ventricular filling pressure and increased myocardial fiber stretch. These patients will present with signs and symptoms of both congestion and hypoperfusion. The treatment goals are to alleviate these signs and symptoms by increasing CI above 2.2 L/min/m^2 and reducing PCWP to 15 to 18 mm Hg while maintaining an adequate mean arterial pressure. Thus, therapy will involve a combination of agents used for subset II and subset III patients to achieve these goals (i.e., combination of diuretic plus positive inotrope). These targets may be difficult to achieve and will necessitate careful monitoring and individualization of drug therapy. Nitroprusside may be a particularly useful agent in this setting because of its mixed arterial–venous vasodilating effects. In the presence of significant hypotension and low mean arterial pressures, inotropic agents with vasopressor activity (e.g., dopamine) may be required initially to achieve an adequate perfusion pressure to essential organs and can then be combined, if necessary, with diuretics and/or therapies to obtain the desired hemodynamic effects and clinical response.

TABLE 22-4 Usual Hemodynamic Effects of Intravenous Agents Commonly Used for Treatment of Advanced or Decompensated Heart Failure[a]

Drug	Dose	HR	MAP	PCWP	CO	SVR
Dopamine	0.5–3 mcg/kg/min	0	0	0	0/+	–
Dopamine	3–10 mcg/kg/min	+	+	0	+	0
Dopamine	10–20 mcg/kg/min	+	+	+	+	+
Dobutamine	2.5–20 mcg/kg/min	0/+	0	–	+	–
Milrinone	0.1–0.75 mcg/kg/min	0/+	0/–	–	+	–
Nitroprusside	0.25–3 mcg/kg/min	0/+	0/–	–	+	–
Nitroglycerin	5–200 mcg/min	0/+	0/–	–	0/+	0/–
Furosemide	20–80 mg IVB (<4 mg/min)[b] 2–3 times/day or 0.1 mg/kg/h CI	0	0/–	–	0	0
Enalaprilat	1.25–2.5 mg every 6–8 h	0	0/–	–	+	–

PHARMACOLOGIC THERAPY OF ACUTE DECOMPENSATED HEART FAILURE

6 Unfortunately, the treatment of decompensated heart failure has not improved substantially in the past decade due in large part to the lack of clinical trial data in this population. The pharmacotherapeutic agents used to treat patients with decompensated heart failure rarely, if ever, produce a single cardiovascular action. Even when intended for a single purpose (e.g., a positive inotrope), other drug effects (tachycardia, vasodilation, or vasoconstriction) may either add to the therapeutic effect or cause adverse events that negate or even outweigh the intended therapeutic benefit. It often can be difficult to anticipate how an individual patient will respond to a given intervention. For this reason, hemodynamic monitoring can be useful, and many drugs are considered first-line therapy due in part to their short half-lives and ease of titration. The description of expected drug actions outlined below should be viewed as a general guide to the clinician, who must continuously reassess the patient for desired outcomes. Table 22–4 contains a summary of the expected hemodynamic effects of the various drugs discussed in the following sections.

DIURETICS[23–26]

7 Intravenous loop diuretics, including furosemide, bumetanide, and torsemide, are used in the management of decompensated heart failure, with furosemide being the most widely studied and used agent in this setting. Bolus administration of diuretics reduces preload within 5 to 15 minutes by functional venodilation and later (>20 minutes) via sodium and water excretion, thereby improving pulmonary congestion. However, the acute reduction in venous return may severely compromise effective preload for patients with significant diastolic dysfunction or intravascular depletion or for those whose CI are significantly dependent on adequate filling pressure (i.e., preload dependent). This reduction in preload may result in a reflex elevation in renin, norepinephrine, and AVP and the expected consequences of arteriolar and coronary constriction, tachycardia, and increased myocardial oxygen consumption. Unlike arterial dilators and positive inotropic agents, diuretics do not cause an upward shift in the Frank–Starling curve or increase CI significantly in most patients (Table 22–4 and Fig. 22–3). In contrast, excessive preload reduction with diuretics, specifically diuresis to PCWP less than 15 mm Hg, can lead to a decline in cardiac output (Fig. 22–3). Furthermore, intravascular depletion may occur in the setting of rapid diuresis despite continued relative total body fluid overload, and thus, daily diuresis goals must be highly individualized. Most patients tolerate a 2 L/day net negative diuresis. However, some end-stage patients, especially those who are malnourished due to early satiety, will only tolerate a 1 L/day net negative diuresis. Thus, diuretics must be used judiciously to obtain the desired improvement in symptoms of congestion while avoiding a reduction in cardiac output, symptomatic hypotension, or worsening renal function. Although counter intuitive, patients with excessive fluid overload may experience compromised cardiac output, and this may improve with diuresis once PCWP reach more near normal ranges. This concept was described earlier in the chapter (Fig. 22–3) and may explain why renal function occasionally improves in the setting of diuresis.

Diuretic Resistance

Occasionally, patients respond poorly to large doses of loop diuretics, and heart failure is the most common clinical setting in which diuretic resistance is observed. Multiple retrospective analyses suggest that diuretics, especially aggressive diuretic administration, may be harmful. The use of diuretics is associated with a dose-dependent increase in mortality.[27] Recent evidence also suggests that high diuretic doses are associated with a decline in renal function in decompensated heart failure,[25,28] which further exacerbates diuretic resistance. Thus, the need for increased exposure to diuretics in the setting of diuretic resistance is concerning.

The mechanisms responsible for diuretic resistance in heart failure patients appear to be both pharmacokinetic and pharmacodynamic.[29] The bioavailability of furosemide is relatively normal in heart failure patients, but the rate of absorption is prolonged approximately twofold, and peak concentrations are reduced approximately 50%. Because loop diuretics have a sigmoidal-shaped urine concentration-response curve, prolonged absorption may result in concentrations that fail to reach the steep portion of this curve, resulting in diminished responsiveness. Despite normal pharmacokinetics following intravenous administration, diuretic resistance is also observed with this route, suggesting an important pharmacodynamic component to diuretic resistance. The decreased responsiveness in heart failure patients is explained in part by the high concentrations of sodium reaching the distal tubule as a result of the blockade of sodium reabsorption in the loop of Henle. As a consequence, the distal tubule hypertrophies, increasing its ability to reabsorb sodium. In addition, neurohormonal activation, low cardiac output, reduced renal perfusion, and subsequent decreased delivery of drug to the kidney may also contribute to resistance.

Several maneuvers can be attempted to overcome diuretic resistance. Current guidelines support one of three options for managing patients who do not initially respond to diuretic therapy.[5,9] First, larger intravenous bolus doses of loop diuretics may achieve concentrations closer to the top of the concentration-response curve. Second a continuous intravenous infusion may be used to maintain more constant concentrations in the steep portion of this curve. Initial studies of continuous-infusion furosemide suggest a greater natriuretic effect and no difference in metabolic adverse effects when compared with the same total daily dose given by intravenous bolus.[9,26,30] More recently, Thomson et al conducted a prospective, randomized, parallel-group study comparing continuous intravenous with intermittent intravenous infusion of furosemide in 56 patients with decompensated heart failure.[31] The

primary end point of the study was net urine output (nUOP) per 24 hours, which was 2098 ± 1132 mL with continuous dosing of intravenous furosemide versus 1575 ± 1100 mL with intermittent dosing ($P = 0.086$). The continuous dosing group had significantly greater total urine output ($P = 0.019$), although mean weight loss was not significantly different between the groups. The continuous dosing group did experience a shorter length of hospital stay ($P = 0.006$). A larger study, the DOSE-AHF Trial, is ongoing and will compare four study arms: low dose and high dose intermittent dosing and low dose and high dose continuous infusion.

Third, a second diuretic with a different mechanism of action can be administered. Combining a loop diuretic with a distal tubule blocker such as oral metolazone, oral hydrochlorothiazide, or intravenous chlorothiazide can produce a synergistic diuretic effect. The synergism is not a pharmacokinetic interaction but is related to the increased delivery of sodium to the distal convoluted tubule. Enhanced sodium delivery to (and reabsorption in) the distal tubule can then be blocked by the thiazide-type diuretic. Thus, when thiazide-type diuretics are added to a loop diuretic, they block more than their normal 5% to 8% of filtered sodium, and the combination results in synergistic natriuresis. The loop diuretic–thiazide combination generally should be reserved for the inpatient setting, where the patient can be monitored closely given the increased likelihood of a more profound diuresis with severe electrolyte and volume depletion. When used in the outpatient setting, very low doses or only occasional doses of the thiazide-type diuretic should be used along with close follow-up (e.g., weight, vital signs, serum potassium, dizziness) to avoid serious adverse events.

Current guidelines support each of the three options described above for managing patients who do not initially respond to diuretic therapy. Further restricting sodium and fluid (e.g., less than 1 g and less than 1 L per day, respectively) beyond that which is routine may also prove useful in managing diuretic refractory patients. Such severe fluid restrictions will also be helpful in managing moderate to severe hyponatremia. Ultrafiltration is an additional therapeutic option in the diuretic refractory patient. This topic is discussed within the section of Mechanical Circulatory Support.

Treatment of heart failure with other agents (e.g., positive inotropes or arterial vasodilators) may improve diuresis by increasing cardiac output and renal perfusion. As previously discussed, given the adverse effects of inotropic therapy, this option is generally reserved for patients not responding to all other therapies or those with apparent low cardiac output. Administration of low doses of dopamine with the hope of enhancing diuresis was previously common practice. However, data suggest that addition of dopamine to furosemide provides no additional diuresis.[32]

POSITIVE INOTROPIC AGENTS[33,34]

8 Drugs that increase intracellular cyclic adenosine monophosphate (cAMP) are the only positive inotropic agents currently approved for the treatment of acute heart failure. β-agonists activate adenylate cyclase through stimulation of β-adrenergic receptors, with the enzyme then catalyzing the conversion of adenosine triphosphate to cAMP. Phosphodiesterase inhibitors raise cAMP concentrations by reducing its degradation. Thus, both drug classes increase intracellular cAMP, which enhances phospholipase (and subsequently phosphorylase) activity, increasing the rate and extent of calcium influx during systole and enhancing contractility. Additionally, cAMP enhances reuptake of calcium by the sarcoplasmic reticulum during diastole, improving active relaxation. The receptor activities of the β-agonists are summarized in Table 22–5. Although rarely used in management of heart failure, the receptor effects of epinephrine, norepinephrine, and isoproterenol are provided for reference.

TABLE 22-5 Relative Effects of Adrenergic Drugs on Receptors

Drug	α_1	β_1	β_2	*Dopamine*$_1$
Dopamine[a]	++++	++++	++	++
Epinephrine	++++	++++	++	0
Norepinephrine	++++	++++	0	0
Phenylephrine	++++	0	0	0
Dobutamine	+	++++	++	0
Isoproterenol	0	++++	++++	0

[a]See text for a more detailed description of the dose-dependent hemodynamic effects.

Digoxin has little, if any, place in the acute treatment of patients with decompensated heart failure who are hemodynamically unstable. The delay in peak inotropic effect, limited inotropic effect, long duration of action, and potential toxicity (arrhythmic, neurologic) are disadvantages in the acute setting. However, for patients with acute decompensation who are taking digoxin as part of their chronic therapy, it is generally unnecessary to adjust the dose or discontinue its use unless changes in renal function increase the risk of toxicity.

Although a number of parenteral agents have been used for the treatment of patients with decompensated heart failure, dobutamine and milrinone have emerged as the two drugs most commonly administered. These drugs differ in their mechanism of action and resulting pharmacologic effects and provide advantages and disadvantages in any given patient.

Dobutamine

Dobutamine, a synthetic catecholamine, is a β_1- and β_2-receptor agonist with some α_1-agonist effects (Table 22–5). Unlike dopamine, dobutamine does not cause release of norepinephrine from nerve terminals. The positive inotropy is primarily a β_1-receptor mediated effect. Cardiac β_1-receptor stimulation by dobutamine causes an increase in contractility but generally no significant change in heart rate and may provide an explanation for the apparently more modest chronotropic actions of dobutamine compared with dopamine. The overall hemodynamic effects of dobutamine are the result of its effects on adrenergic receptors and reflex-mediated actions. Modest peripheral β_2-receptor-mediated vasodilation will tend to offset minor α_1-receptor-mediated vasoconstriction with dobutamine. In addition, the increase in cardiac output will often cause a reflexive decline in systemic vascular resistance. Thus the net vascular effect is usually vasodilation.

The overall hemodynamic effects of dobutamine are those of a potent inotropic agent with vasodilating action. Initial doses of 2.5 to 5 mcg/kg per minute can be increased progressively to 20 mcg/kg/min based on clinical and hemodynamic responses. The onset of action is within minutes; however, peak effects may take 10 minutes to become evident. Dobutamine has a half-life of 2 minutes. Cardiac index is increased because of inotropic stimulation, arterial vasodilation, and a variable increase in heart rate. Because of the offsetting changes in arteriolar resistance and CI, dobutamine usually will cause relatively little change in mean arterial pressure, although these effects may be variable. This is compared with the more consistent increase observed with dopamine. Dobutamine's vasodilating action usually reduces PCWP, making it particularly useful in the presence of low CI and an elevated left ventricular filling pressure, or detrimental in the presence of a reduced filling pressure. Unfortunately, an increase in oxygen consumption with dobutamine has been demonstrated for patients with both ischemic and nonischemic cardiomyopathy. The major adverse effect of dobutamine is tachycardia. While concern over attenuation of dobutamine's hemodynamic effects has been raised

with prolonged administration, some effect is likely still retained. Thus, dobutamine dose should be tapered rather than abruptly discontinued.

For some patients, dobutamine (or milrinone) dose reduction or discontinuation results in acute decompensation, and these patients may then require placement of an indwelling intravenous catheter for continuous therapy. This approach may be used to "bridge" patients awaiting cardiac transplantation or left ventricular assist device and may also be used to facilitate the discharge of patients who are not transplant candidates but who cannot be weaned from inotrope therapy. In this latter group, the use of continuous outpatient dobutamine therapy is for palliative use and should only be considered after multiple unsuccessful attempts to maximize oral therapy and discontinue inotrope therapy. Although effective for symptom palliation, it should be realized that the risk of mortality is likely increased. In contrast, the use of regularly scheduled intermittent dobutamine infusions is not recommended in the current guidelines.[5,9]

Milrinone

Milrinone is a bipyridine derivative that inhibits phosphodiesterase III, an enzyme responsible for the breakdown of cAMP to AMP. Milrinone has supplanted the use of amrinone, the prototype drug for milrinone, given the more frequent occurrence of thrombocytopenia with amrinone. Milrinone's positive inotropic, arterial vasodilating, and venous vasodilating effects contribute to the therapeutic response in heart failure patients; hence, milrinone has been referred to as an *inodilator*. The relative balance of these pharmacologic effects may vary with dose and underlying cardiovascular pathology.

During intravenous administration, there is an increase in stroke volume (and, therefore, cardiac output) with little change in heart rate (Table 22–4). Despite the increase in CI, mean arterial pressure may remain constant due to a concomitant decrease in arteriolar resistance. In contrast, the vasodilating effects may predominate and lead to a decrease in blood pressure and a reflex tachycardia. Like dobutamine, milrinone lowers PCWP by venodilation and thus is particularly useful for patients with a low CI and an elevated left ventricular filling pressure. Such a reduction in preload, however, can be hazardous for patients without excessive filling pressure (especially those with subset III heart failure), leading to further decline in CI. Such an effect would blunt the improvement in cardiac output that would otherwise be produced by the positive inotropic and arterial dilating actions. Milrinone should be used cautiously as a single agent in severely hypotensive heart failure patients because it will not increase, and may even decrease, arterial blood pressure. The results of controlled studies comparing dobutamine with milrinone indicate that these agents produce generally similar hemodynamic effects. A clinically insignificant but greater increase in heart rate with dobutamine is the most consistent difference in these studies.

Milrinone has a longer terminal elimination half-life than other adrenergic agonists. The average milrinone half-life in healthy subjects is about 1 hour and approximately 3 hours for patients with heart failure. This long elimination half-life may be a disadvantage in this patient population because a loading dose may be necessary to obtain a prompt initial response, minute-to-minute titrations in dose cannot be made based on response, and adverse effects (arrhythmias or hypotension) will persist longer after drug discontinuation. The usual loading dose for milrinone is 50 mcg/kg administered over 10 minutes. However, if rapid hemodynamic changes are not necessary, the loading dose should be eliminated given an increased risk of hypotension. Thus, most patients are simply started on the maintenance infusion without a preceding bolus dose. Lower initial doses, such as 0.1 mcg/kg/min, may be considered. The maintenance infusion for milrinone is commonly 0.1 to 0.3 mcg/kg/min (up to 0.75 mcg/kg/min). Milrinone is excreted unchanged in urine, and thus, its infusion rate should be decreased by 50% to 70% for patients with significant renal impairment.

The most notable adverse events associated with milrinone are arrhythmia, hypotension, and thrombocytopenia. While the incidence of thrombocytopenia associated with milrinone therapy is rare, patients should still have platelet counts determined before and during therapy.

The combination of dobutamine and milrinone would be expected to produce additive effects on CI and PCWP reduction, suggesting this regimen as an option for patients who have dose-limiting adverse effects with either drug class. It is unclear, however, if this combination provides a therapeutic advantage over the combination of a positive inotrope and a traditional pure vasodilator such as nitroprusside.

One study with milrinone points out the risk associated with routine administration of inotropic therapy to a broad population of patients admitted to the hospital for decompensated heart failure. Although this approach is not supported by clinical trial data, many patients without signs or symptoms of hypoperfusion receive milrinone or other inotropic therapy with the belief that the hemodynamic effects may shorten hospitalization and improve clinical outcomes. Designed to evaluate this strategy, the Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure (OPTIME-CHF) trial was a randomized, double-blind trial comparing the effects of milrinone and placebo for patients hospitalized with an acute exacerbation of chronic heart failure who, in the investigator's opinion, did not require inotropic therapy.[7] The 949 patients received a 48-hour infusion of milrinone 0.5 mcg/kg/min with no loading dose or placebo. No difference between milrinone and placebo was found in the primary end point, the number of days patients were hospitalized for cardiovascular causes within 60 days of randomization. However, adverse events were more common in the milrinone group. Sustained hypotension requiring intervention (10.7% vs 3.2%; $P < 0.001$) and new onset of atrial fibrillation or flutter (4.6% vs 1.5%; $P = 0.004$) occurred more frequently for patients receiving milrinone.

Recently, data from the ADHERE Registry ($n = 15,230$) was used to compare in-hospital mortality with intravenous nitroglycerin, nesiritide, milrinone, or dobutamine. After adjusting for baseline parameters that predict in-hospital mortality, both dobutamine- and milrinone-treated patients had a higher in-hospital mortality when compared to patients receiving either nitroglycerin or nesiritide ($P < 0.005$). There was no difference in in-hospital mortality between nitroglycerin- and nesiritide-treated patients ($P = 0.58$). In-hospital mortality was higher for patients receiving dobutamine compared to milrinone ($P = 0.027$).[35]

These results add to the growing concern regarding the use of inotropic drugs for patients with decompensated heart failure and strongly suggest that milrinone, and probably other inotropes, should not be routinely used for the treatment of acute heart failure exacerbations. Although the routine use of milrinone should be discouraged, clinicians should be aware that inotropic therapy may be needed in selected patients such as those with low cardiac output states with organ hypoperfusion or with cardiogenic shock.[5,9] Generally, milrinone should be considered for patients who are receiving chronic β-blocker therapy because its positive inotropic effect does not involve stimulation of β-receptors. In contrast to dobutamine, milrinone's positive hemodynamic effects persist despite concomitant β-blocker therapy.

Dopamine

Although dopamine generally should be avoided in the treatment of decompensated heart failure, the only clinical scenario where its pharmacologic actions may be preferable to dobutamine or milrinone is for the patient with marked systemic hypotension or cardiogenic shock in the face of elevated ventricular filling pressures, where dopamine in doses greater than 5 mcg/kg/min may be necessary to raise central aortic pressure. However, there are no data to support this commonly employed practice.

Dopamine, the endogenous precursor of NE, exerts its effects by directly stimulating adrenergic receptors as well as causing release of NE from adrenergic nerve terminals. Dopamine produces dose-dependent hemodynamic effects because of its relative affinity for α_1-, β_1-, β_2-, and D1- (vascular dopaminergic) receptors (see Table 22–5). The following dose-dependent actions are intended as a general guide to the clinician.

Positive inotropic effects mediated primarily by β_1-receptors become more prominent with dopamine doses of 2 to 5 mcg/kg/min. Cardiac index is increased because of an increase in stroke volume and a variable increase in heart rate, which is partially dose dependent. There is usually little change in systemic vascular resistance, presumably because neither vasodilation (D1- and β_2-receptor-mediated) nor vasoconstriction (α_1-receptor-mediated) predominates. At doses between 5 to 10 mcg/kg/min, chronotropic and α_1-receptor-mediated vasoconstricting effects become more prominent. Mean arterial pressure usually increases due to an increase in both CI and systemic vascular resistance (Table 22–4). The vasoconstricting effects of higher doses could indirectly limit the increase in CI by increasing afterload and PCWP, thus complicating the management of patients with preexisting high afterload. For such patients, alternative agents (dobutamine, milrinone) or the addition of diuretics and/or vasodilators may be necessary.

Dopamine, particularly at higher doses, may alter several parameters that increase myocardial oxygen demand (increased heart rate, contractility, and systolic pressure) and potentially decrease myocardial blood flow (coronary vasoconstriction and increased wall tension), worsening ischemia in some patients with coronary disease. As with dobutamine and milrinone, arrhythmogenesis is also more common at higher doses.

VASODILATORS[25,36]

9 10 As previously discussed, activation of the sympathetic nervous system, renin angiotensin system, and other mediators results in vasoconstriction and increased systemic vascular resistance as well as fluid retention and increased PCWP. The influence of individual vasodilators on these hemodynamic parameters varies depending on the unique properties of each agent (Fig. 22–4). Agent selection should be based upon individual patient presentation and, if available, hemodynamic parameters.

Vasodilators typically are described by their prominent site of action (arterial or venous). Arterial vasodilators act as impedance-reducing agents, reducing afterload and causing a reflexive increase in cardiac output. Venodilators act as preload reducers by increasing venous capacitance, reducing symptoms of pulmonary congestion for patients with high cardiac filling pressures. Mixed vasodilators act on both resistance and capacitance vessels, reducing congestive symptoms while increasing cardiac output. Nitroprusside, nitroglycerin, and nesiritide are the most commonly used intravenous vasodilating agents in decompensated heart failure.

Nitroprusside

Sodium nitroprusside, a mixed arterial–venous vasodilator, acts on vascular smooth muscle, increasing synthesis of nitric oxide

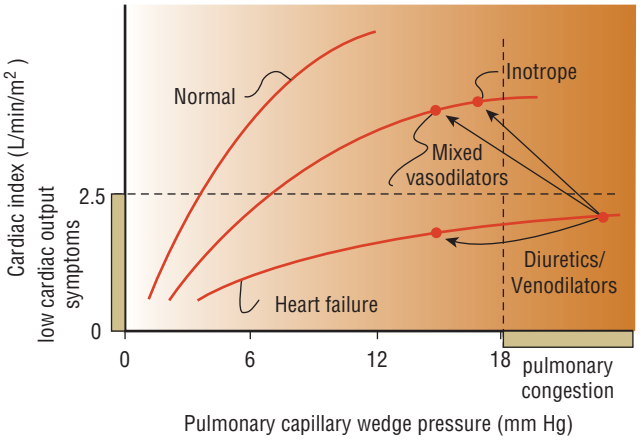

FIGURE 22-4. Relationship between cardiac output and pulmonary capillary wedge pressure. See text for more detailed description of how various vasodilators and inotropes influence these hemodynamic parameters.

to produce its balanced vasodilating action. As such, it increases CI and decreases venous pressure. Nitroprusside's effects on these parameters are qualitatively similar to those produced by dobutamine and phosphodiesterase inhibitors, despite the fact that it has no direct inotropic activity (Table 22–4). However, nitroprusside generally causes a greater decrease in PCWP, systemic vascular resistance, and blood pressure than these agents do. Mean arterial pressure may remain fairly constant but often decreases, depending on the relative increase in cardiac output and reduction in arteriolar tone. Hypotension is an important dose-limiting adverse effect of nitroprusside and other vasodilators. Therefore, this drug is used primarily for patients who have a significantly elevated systemic vascular resistance and often requires invasive hemodynamic monitoring.

Patients with normal left ventricular function will not experience an increase in stroke volume when systemic vascular resistance falls because the normal ventricle is fairly insensitive to small changes in afterload. Consequently, these patients experience a significant decrease in blood pressure after administration of arterial vasodilators. This explains why nitroprusside is a potent antihypertensive agent for patients without heart failure but causes less hypotension and reflex tachycardia for patients with left ventricular dysfunction. Nonetheless, even a modest increase in heart rate could have adverse consequences for patients with underlying ischemic heart disease and/or resting tachycardia, and close monitoring is necessary during therapy.

Nitroprusside has been studied extensively and shown to be effective in the short-term management of patients with severe heart failure in a variety of settings (i.e., acute MI, valvular regurgitation, after coronary bypass surgery, decompensated chronic heart failure). Generally, nitroprusside will not worsen, and may improve, the balance between myocardial oxygen demand and supply. This is mainly due to a decrease in oxygen demand caused by the lowering of left ventricular wall tension and a possible increase in subendocardial blood flow resulting from decreased left ventricular end-diastolic pressure. However, an excessive decrease in systemic arterial pressure can reduce coronary perfusion and worsen ischemia, leading to an increased risk of coronary steal.

Nitroprusside has a rapid onset of action and duration of action of less than 10 minutes, necessitating its administration by continuous intravenous infusion. This allows for precise dose titration based on measured clinical and hemodynamic parameters. It, like other vasodilators used in heart failure, should be initiated at a low dose (0.1 to 0.2 mcg/kg/min) to avoid excessive hypotension and then increased by small increments (0.1 to 0.2 mcg/kg/min) every 5 to 10 minutes

as needed and tolerated. Usually effective doses range from 0.5 to 3.0 mcg/kg/min. A rebound phenomenon has been reported after abrupt withdrawal of nitroprusside for patients with heart failure and is apparently due to reflex neurohormonal activation during therapy. If renal perfusion pressure is compromised by the drug, salt and water retention can contribute to volume expansion and tachyphylaxis; this is seen typically only for patients with chronic hypertension, baseline azotemia, or when therapeutic augmentation of cardiac output during therapy is minimal. When stopping nitroprusside and switching to oral drugs, it is usually advisable to taper doses slowly. Nitroprusside can cause cyanide and thiocyanate toxicity, but these are very unlikely when doses less than 3 mcg/kg/min are administered for less than 3 days, except for patients with a serum creatinine level greater than 3 mg/dL. Nitroprusside should not be used in the presence of elevated intracranial pressure because it may worsen cerebral edema in this setting. Given the potent pulmonary vasodilator effects of nitroprusside as well as its short half-life, this agent is frequently used to determine reversibility of pulmonary hypertension for patients being assessed for heart transplantation. This is the most common use of nitroprusside for the management of decompensated heart failure.

Nitroglycerin

Intravenous nitroglycerin is often considered the preferred agent for preload reduction for patients with severe heart failure. Because of its short half-life, intravenous nitroglycerin is administered by continuous infusion. Its major hemodynamic actions are reductions in preload and PCWP via functional venodilation and mild arterial vasodilation that is particularly evident in patients with heart failure and elevated systemic vascular resistance or when given in doses approaching 200 mcg/min (Table 22–4). Intravenous nitroglycerin is used primarily as a preload reducer for patients with pulmonary congestion. In higher doses, nitroglycerin displays potent coronary vasodilating properties and beneficial effects on myocardial oxygen demand and supply, making it the vasodilator of choice for patients with severe heart failure and ischemic heart disease.

Nitroglycerin should be initiated at a dose of 5 to 10 mcg/min (0.1 mcg/kg/min) and increased every 5 to 10 minutes as necessary and tolerated. Hypotension and an excessive decrease in PCWP are important dose-limiting side effects. Maintenance doses usually vary from 35 to 200 mcg/min (0.5 to 3.0 mcg/kg/min). While tolerance to the hemodynamic effects of nitroglycerin may develop over 12 to 72 hours of continuous administration, some patients experience a sustained response. Like nitroprusside, nitroglycerin should not be used in the presence of elevated intracranial pressure because it may worsen cerebral edema in this setting.

Nesiritide

Nesiritide is the first new drug approved for the treatment of decompensated heart failure since milrinone. Manufactured by recombinant techniques, it is identical to the endogenous human BNP secreted by the ventricular myocardium in response to volume overload. Exogenous administration of nesiritide mimics the vasodilator and natriuretic actions of the endogenous peptide by stimulating the natriuretic peptide receptor A, which leads to increased levels of cGMP in target tissues. Nesiritide produces dose-dependent venous and arterial vasodilation, increases cardiac output, natriuresis, and diuresis, and decreases cardiac filling pressures, sympathetic nervous system, and renin–angiotensin–aldosterone system activity. Unlike nitroglycerin or dobutamine, tolerance does not develop to nesiritide's pharmacologic actions. It does not affect cAMP or stimulate β-receptors, mechanisms that are thought to contribute to the myocardial toxicity associated with the positive inotropic agents. Thus, nesiritide does not have the proarrhythmic effects related with inotropic therapy. Nesiritide is eliminated by several pathways including the natriuretic peptide receptor C on target tissues, proteolytic cleavage by neutral endopeptidase, and renal filtration. Its elimination half-life of 18 minutes is considerably longer than that of other intravenous vasoactive agents.

The Vasodilation in the Management of Acute CHF (VMAC) trial was a randomized, double-blind trial that compared the effects of nesiritide, IV nitroglycerin, or placebo for patients with decompensated heart failure and dyspnea receiving standard background therapy.[8] Patients received pulmonary artery catheterization at the discretion of the investigators. The primary study end points were the patient's self-assessment of dyspnea (all patients) and the change in PCWP at 3 hours after the start of the study drug infusion (only for patients with a pulmonary artery catheter) compared to placebo. Nesiritide significantly reduced PCWP at 3 hours compared to placebo and nitroglycerin. Although nesiritide reduced dyspnea at 3 hours compared to placebo, no difference between nesiritide and nitroglycerin was found.

The precise role of nesiritide in the pharmacotherapy of decompensated heart failure remains controversial. Some of this controversy centers on the marginal lack of improvement in mortality or other clinical outcomes with nesiritide compared to nitroglycerin (or nitroprusside) balanced against nesiritide's significantly greater costs (~$450 for a 24-hour nesiritide infusion compared to $10 to $15 for nitroglycerin). In addition, two metaanalyses suggested an increased risk of negative outcomes with nesiritide: the first, an increased risk of worsening renal function and the second, an increased risk in mortality.[37,38] The authors of these studies concluded that these finding are hypothesis generating and should be further investigated. To clarify these issues about the safety and efficacy of nesiritide, its manufacturer is conducting an additional prospective randomized controlled trial, the Double-Blind, Placebo-Controlled, Multicenter Acute Study of Clinical Effectiveness of Nesiritide in Subjects With Decompensated Heart Failure (ASCEND-HF) trial.

VASOPRESSIN RECEPTOR ANTAGONISTS

Fluid balance depends on the relative concentrations of sodium and water. Abnormally low sodium concentrations or hyponatremia, commonly defined as a serum sodium less than 125 mmol/L, can arise from a variety of causes. Diuretic administration can cause hypovolemic hyponatremia or excessive water consumption or result in euvolemic hyponatremia (urine sodium less than 30 mmol/L), and heart failure can be associated with hypervolemic hyponatremia (urine sodium greater than 30 mmol/L). There are many other causes of hyponatremia including, but not limited to, syndrome of inappropriate diuretic hormone (SIADH), cirrhosis with ascites and certain medications.[39]

Hyponatremia is commonly characterized by inappropriately elevated concentrations of AVP, which is also known as *antidiuretic hormone*. In the setting of heart failure, excess total body volume exceeds excess total body sodium. Arterial baroreceptors stimulate increased AVP release and net water retention. While the prevalence of hyponatremia in heart failure varies with definition, the Acute and Chronic Therapeutic Impact of Vasopressin Antagonists in Heart Failure (ACTIV-HF) trial found that approximately 20% of patients admitted to the hospital for acute heart failure had hyponatremia, defined as a serum sodium less than 136 mmol/L.[40] Importantly, the presence of hyponatremia is associated with increased mortality in heart failure patients.[41]

While the majority of cases of hyponatremia are mild, asymptomatic, and self-limited, the primary concern is the less common but life-threatening presentation that may include lethargy, confusion, respiratory arrest, cerebral edema, seizures, and coma, which

may result in death. Thus, prompt diagnosis and management is critical. Treatment is specific to the underlying etiology, duration of symptoms, and severity of symptoms. Treatment may include removal of the underlying cause, fluid restriction, isotonic or hypertonic saline administration, and/or administration of diuretics, vasopressin antagonists, or other therapies. Importantly, while neurological sequelae may occur if treatment is not initiated promptly, overly rapid correction of hyponatremia (greater than 12 mmol/L per 24 hours) results in the same.[42]

Currently available vasopressin receptor antagonists affect one or two AVP receptors, V_{1A} or V_2.[43] Present in the vascular smooth muscle cells and myocardium, stimulation of V_{1A} results in vasoconstriction as well as myocyte hypertrophy, coronary vasoconstriction, and positive inotropic effects. The V_2 receptors are present in the renal tubules where they regulate water reabsorption. Tolvaptan selectively binds to and inhibits the V_2 receptor, whereas conivaptan nonselectively inhibits both the V_{1A} and V_2 receptor. Tolvaptan is an oral agent indicated for hypervolemic and euvolemic hyponatremia for patients with SIADH, cirrhosis, and heart failure. Importantly, tolvaptan is a substrate of cytochrome P450-3A4 and contraindicated with potent inhibitors of this enzyme. Tolvaptan is typically initiated at 15 mg orally daily and then titrated to 30 or 60 mg as needed to resolve hyponatremia. Conivaptan is an intravenous agent indicated for hypervolemic and euvolemic hyponatremia due to a variety of causes; however, it is not indicated for hyponatremia associated with heart failure, and thus it will not be further discussed. Patients receiving either agent must be monitored closely to avoid an overly rapid rise in serum sodium. If serum sodium rises too rapidly, hypotension or hypovolemia can occur, and the vasopressin antagonist should be discontinued. Therapy may be restarted at a lower dose if hyponatremia recurs or persists and/or these side effects resolve.[44]

In the Studies of Ascending Levels of Tolvaptan in Hyponatremia 1 and 2 (SALT-1 and SALT-2) trials, tolvaptan effectively increased serum sodium at 4 and 30 days in euvolemic or hypervolemic patients; approximately one third of the patients had heart failure as the etiology of hyponatremia.[45] The Efficacy of Vasopressin Antagonism in Heart Failure Outcome Study With Tolvaptan (EVEREST) trial was conducted in 4,133 patients hospitalized with NYHA class III-IV heart failure who experienced significant improvement in hyponatremia with tolvaptan compared with placebo.[46,47] In addition, patients experienced an improvement in diuresis, as well as signs and symptoms of congestion. Unfortunately, this study failed to demonstrate an improvement in global clinical status at discharge or a reduction in 2-year all-cause mortality, cardiovascular mortality, and heart failure rehospitalization. Thus, the role of vasopressin antagonists in the long-term management of heart failure remains unclear.

Overall, tolvaptan was very well tolerated in these trials with the most common side effects being dry mouth, thirst, urinary frequency, constipation, and hyperglycemia. It is important to recognize that while tolvaptan is an oral agent, it was initiated in clinical trials in the inpatient setting where serum sodium and volume status were closely monitored. This is an important safety aspect of this therapy that cannot be over emphasized. Two other vasopressin antagonists are currently being investigated: lixivaptan and satavaptan.

MECHANICAL CIRCULATORY SUPPORT[48]

INTRAAORTIC BALLOON PUMP

The intraaortic balloon pump (IABP) is a form of mechanical circulatory assistance occasionally employed for patients with advanced heart failure who do not respond adequately to drug therapy such as those with intractable myocardial ischemia or patients in cardiogenic shock. The IABP consists of a polyethylene balloon mounted on a catheter that is usually inserted percutaneously into the femoral artery, and the balloon is then advanced into the descending thoracic aorta. During counterpulsation, the balloon is synchronized with the ECG so that it inflates during diastole and displaces aortic blood, thus increasing aortic diastolic pressure and coronary perfusion. The balloon deflates just prior to the opening of the aortic valve during systole and causes a sudden decrease in aortic pressure, allowing the left ventricle to pump against reduced arterial impedance. IABP support results in increased CI, coronary artery perfusion, and myocardial oxygen supply accompanied by decreased myocardial oxygen demand. Thus, it is particularly useful for short-term use for patients with decompensated heart failure in the setting of myocardial ischemia (evolving infarction, patients awaiting emergency coronary bypass surgery). It is also used in hemodynamically unstable patients who are unresponsive to inotropic therapy. In the latter circumstance, the IABP may serve as a bridge to a surgical device or transplantation. Intravenous vasodilators and inotropic agents generally are used in conjunction with the IABP to maximize hemodynamic and clinical benefits.

VENTRICULAR ASSIST DEVICES[49]

⓬ A number of ventricular assist devices (VAD) are available or under investigation. These pumps are surgically implanted and assist, or in some cases replace, the pumping functions of the right and/or left ventricles. A left VAD (LVAD) removes blood directly from the left ventricle or the left atrium and pumps it to the aorta. The right VAD works similar to the LVAD and may be used alone or in conjunction with the LVAD.

LVADs can be used in the short-term (days to a couple of weeks) for temporary stabilization of a patient awaiting an intervention that would correct the underlying cardiac dysfunction. Alternatively, these devices can be used in the long term (several months to a couple of years) as a bridge to heart transplantation. More recently, permanent device implantation has become an option for patients who are not heart transplant candidates.

The Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial randomized 129 patients with decompensated heart failure who were ineligible for transplant to the HeartMate VE LVAD (Thoratec Corp., Pleasanton, CA) or optimal medical therapy. LVAD patients experienced improved 1- and 2-year survival (52% vs 25% at 1 year and 23% vs 8% at 2 years, $P = 0.009$); however, the overall survival was admittedly low in both groups.[50] The REMATCH trial was responsible for the approval of the use of these devices as "destination" therapy—destination being the last therapeutic option for a patient who is not a transplant candidate. More recently, the Investigation of Non-Transplant Eligible Patients who are Inotrope Dependent (INTrEPID) trial evaluated the Novacor LVAD (WorldHeart, Ottawa, Canada) in an inotrope-dependent heart failure population. Although the 1-year survival was improved in the LVAD arm (21% vs 11% in medically treated patients, $P = 0.02$), overall outcomes in the LVAD arm were inferior to those of the HeartMate VE in the REMATCH trial. Some of the patients in the INTrEPID trial were much sicker and thus would have been considered too high risk for surgery in the REMATCH trial.[51] Despite modifications leading to the HeartMate XVE design to improve safety and reliability of the device, long-term survival in the post-REMATCH era did not appreciably change (56% vs 51% 1-year survival).[52] In the post-REMATCH era, complications were unrelated to device malfunction and thus the role of operative candidate selection and the critical need to identify the "optimal" window for LVAD implantation was emphasized. Ongoing studies are assessing

the next generation axial flow device, the HeartMate II LVAD (Thoratec Corporation), as well as making direct comparisons of various devices. These studies have also raised awareness regarding some of the limitations of these devices. Complications with LVADs include bleeding, air embolism, right ventricular failure, as well as those associated with a major surgical procedure including infection. In addition, these pumps can cause hemolysis, thrombosis, renal and hepatic dysfunction, and arrhythmias. Finally, device malfunction may occur. Controversy exists regarding the cost of such procedures given the already significant economic impact of this disease state on the healthcare system.[53] Although only a small number of patients were studied, recent research suggests that prolonged unloading of the left ventricle with an LVAD in combination with drug therapy to induce reverse remodeling can produce sustained recovery in LV function and amelioration of symptoms.[54] Furthermore, data that are more recent suggest that patients referred for LVAD prior to major complications of heart failure developing experience improved survival.[52]

For complete heart replacement therapy, the total artificial heart systems continue to be investigated; however, embolic complications as well as the large size of the currently available systems are limiting their use. Inserted percutaneously, catheter-based LVADs are a more recent advancement. These small pumps may offer an advantage as they avoid the need for open-heart surgery; however, this technology is still in developmental stages.

ULTRAFILTRATION

Renal dysfunction often occurs in the setting of decompensated heart failure, and thus, renal replacement therapy may be necessary. Ultrafiltration provides an additional modality for fluid removal by rapidly removing salt and water (up to 500 mL/hr) in a predictable manner. It has been shown to reduce PCWP and increases diuresis without adversely affecting blood pressure, heart rate, or renal function. In addition, ultrafiltration has been proposed to be safer than diuretics because removal of sodium and water is isotonic. Potential candidates for ultrafiltration include patients with diuretic resistance, renal impairment with diuretic administration, or renal impairment despite inotropic therapy. Complications of ultrafiltration include those associated with central venous access such as infection as well as those associated with rapid volume removal and intravascular depletion. Electrolyte depletion is less significant but still requires close monitoring.

Small studies suggest that ultrafiltration is an effective method to remove fluid in heart failure patients and that early initiation prior to intravenous diuretics was effective and safe in reducing hospital length of stay and readmission in diuretic resistant patients. Recently, the Ultrafiltration versus Intravenous Diuretics for Patients Hospitalized for Acute Decompensated Congestive Heart Failure (UNLOAD) trial investigated the effects of early ultrafiltration alone compared to intravenous diuretics alone in 200 patients hospitalized for decompensated heart failure and evidence of fluid overload. The primary end point of weight loss after 48 hours was significantly greater in the ultrafiltration group (5.0 kg) than in the diuretic group (3.1 kg). There was no significant difference between the two treatment groups in the dyspnea score at 48 hours, another primary end point. Compared with the diuretic group, the net fluid loss was significantly greater in the ultrafiltration group (4.6 L vs 3.3 L) after 48 hours. After 90 days, the incidence and duration of rehospitalization and the incidence of unscheduled office or emergency department visits were significantly lower for patients treated using ultrafiltration than for patients treated with intravenous diuretics.[55] Larger studies are ongoing to determine the role of ultrafiltration in managing decompensated heart failure.

SURGICAL THERAPY

Orthotopic cardiac transplantation remains the best therapeutic option for patients with chronic, irreversible NYHA class IV heart failure, with a 10-year survival of approximately 50% in well-selected patients.[56] Unfortunately, the shortage of acceptable donor hearts has resulted in long waiting times for transplantation with many patients succumbing to their disease prior to transplantation. Another large percentage of patients is rejected from consideration for transplant because of age, concurrent illnesses, psychosocial factors, and other reasons. The shortage of donor hearts has prompted development of new surgical techniques, including ventricular aneurysm resection, mitral valve repair, and myocardial cell transplantation, which have resulted in variable degrees of symptomatic improvement. Further development of these and other techniques may offer additional options for patients who are not candidates for transplantation.

PREPARATION FOR HOSPITAL DISCHARGE

For patients hospitalized with decompensated heart failure, all factors contributing to decompensation should be addressed. Patients should be near if not at optimal fluid status and transitioned from intravenous to oral diuretic therapy. Both the patient and family should receive appropriate education (see details in the following paragraphs). Chronic drug therapy should be optimized and appropriate follow-up clinic appointments scheduled. Typically, patients should be seen in the clinic within 7 to 10 days of hospital discharge. For patients with recurrent hospital admissions, additional discharge criteria should be considered (Table 22–6).[5,9]

Patient education is essential in the discharge process and should be multidisciplinary involving input from dietitians, pharmacists, and other healthcare providers. Teaching should promote self-care by incorporating identification of specific positive and negative behaviors. By having a better understanding of the key concepts of the disease and its management, patient self-care should improve and future hospitalizations may be avoided.[9]

While all patients would benefit from education, those with more severe symptoms (NYHA class III or IV) will require the most

TABLE 22-6 Discharge Criteria for Patients with HF

Recommended for all HF patients	• Exacerbating factors addressed • At least near optimal volume status achieved • Transition from intravenous to oral diuretic successfully completed • Patient and family education completed. • At least near optimal pharmacologic therapy achieved • Follow-up clinic visit scheduled, usually for 7–10 days
Should be considered for patients with advanced HF or recurrent admissions for HF	• Oral medication regimen stable for 24 hours • No intravenous vasodilator or inotropic agent for 24 hours • Ambulation before discharge to assess functional capacity after therapy • Plans for postdischarge management (scale present in home, visiting nurse or telephone follow-up generally no longer than 3 days after discharge) • Referral for disease management

Data from Adams KF, Lindenfeld J, Arnold JMO, et al. HFSA 2006 Comprehensive Heart Failure Practice Guidelines. J Cardiac Fail 2006;12:e1–e122.

intensive counseling. During a hospitalization, only essential education is recommended and should be supplemented within a couple of weeks after discharge in the clinic setting. Patients recently hospitalized for heart failure should be considered for referral to a disease management program.

For patients with end-stage disease, quality of life and prognosis should be discussed with the patient and caregivers. If possible, this discussion should occur while the patient is still able to participate in the decision-making process. End-of-life care should be considered for patients with persistent symptoms at rest despite multiple attempts to optimize therapy as evidenced by: frequent hospitalizations, ongoing limited quality of life, requiring intermittent or continuous intravenous therapy, or consideration of assist devices as destination therapy. In such cases, inactivation of an implantable cardioverter–defibrillator should be discussed and patients may be considered for hospice services.[9] Integration of a palliative care approach may be necessary. As clinical status deteriorates and medical therapies become ineffective, healthcare providers should transition from focusing on mortality reduction to palliative care.[57]

PHARMACOECONOMIC CONSIDERATIONS

Heart failure imposes a tremendous economic burden on the healthcare system. For patients over age 65, it is the most common reason for hospitalization, with hospital admission rates for this disorder continuing to increase. Heart failure is also associated with unacceptably high readmission rates during the 3 to 6 months after initial discharge. Current estimates of costs of heart failure treatment in the United States approach $37 billion with most of the costs associated with hospitalization.[1] The prevalence of heart failure and the costs associated with patient care are expected to increase as the population ages and as survival from ischemic heart disease is improved. Thus, approaches to improve the quality and cost-effectiveness of care for these patients may have a significant impact on healthcare costs. Finally, LVADs as a bridge to heart transplantation were found to be cost-ineffective unless costs associated with their implantation decrease or their clinical benefits increase.[58]

As the management of heart failure has become increasingly complex, the development of disease management programs that use multidisciplinary teams has been studied extensively. These programs utilize several broad approaches, including heart failure specialty clinics and/or home-based interventions. Most are multidisciplinary and may include physicians, advanced practice nurses, dieticians, and pharmacists. In general, programs focus on optimization of drug and nondrug therapy, patient and family education and counseling, exercise and dietary advice, intense follow-up by telephone or home visits, and monitoring and management of signs and symptoms of decompensation. In general, multidisciplinary disease management programs reduce mortality, heart failure and all-cause hospitalizations, and costs.[59]

Pharmacists can play an important role in the multidisciplinary team management of heart failure.[60,61] Compared with conventional treatment, pharmacist interventions that included medication evaluation and therapeutic recommendations, patient education and follow-up telephone monitoring reduced hospitalizations for heart failure. Adherence to guideline-recommended therapy also improved with pharmacist intervention. A recent study found that pharmacist intervention improved medication adherence and reduced emergency department visits and hospitalizations in low-income patients with heart failure.[62] Thus, the role and cost benefits of pharmacist involvement in the multidisciplinary care of heart failure patients are now apparent and should include optimizing doses of heart failure drug therapy, screening for drugs that exacerbate heart failure, monitoring for adverse drug effects and drug interactions, educating patients, and patient follow-up.

CURRENT CONTROVERSIES

1. The optimal pharmacotherapy for patients with acute decompensated heart failure that are refractory to diuretic therapy is controversial. The following questions remain unaddressed by the current literature: change to continuous infusion loop diuretic versus addition of thiazide diuretic, which thiazide diuretic should be added (metolazone, HCTZ, other) and at what dose, high dose versus low dose continuous infusion, and the role of ultrafiltration. Ongoing studies such as the DOSE-AHF trial should address these questions.
2. The role of nesiritide remains highly controversial. After two metaanalyses suggested that nesiritide use is associated with worsening renal function and increased mortality, prescribing of nesiritide has declined considerably. However, the safety of other vasodilators such as nitroglycerin or nitroprusside is not well established, and the use of positive inotropes is associated with poor outcomes. The results of the ongoing ASCEND trials will address both the efficacy and safety of this agent.
3. The role of vasopressin antagonists beyond managing hypervolemic or euvolemic hyponatremia in heart failure patients remains unclear. Future trials addressing impact on long-term outcomes in heart failure patients including morbidity and mortality are warranted.
4. Evolving data regarding the role of LVADs as a bridge to transplant or destination therapy provide further support for the use of these therapeutic modalities. Additional data are warranted to further define the most optimal candidates, timelines for insertion, and how to best minimize complications associated with these mechanical devices.

EVALUATION OF THERAPEUTIC OUTCOMES

Assessment of adequacy of therapy in the acute decompensated HF patient can be separated into two general categories: initial improvement of physiologic parameters and safe discharge from the intensive care unit following conversion to a chronic oral therapeutic regimen. Both goals are equally important because hemodynamic improvement alone has not been correlated with prolonged symptom improvement or enhanced survival.

Initial stabilization requires achievement of adequate arterial oxygen saturation and content. Cardiac index and blood pressure must be sufficient to ensure adequate organ perfusion, as assessed by alert mental status, creatinine clearance sufficient to prevent metabolic azotemic complications, hepatic function adequate to maintain synthetic and excretory functions, a stable heart rate and rhythm (predominately sinus rhythm, rate-stabilized atrial fibrillation or flutter, or paced rhythm), absence of ongoing myocardial ischemia or infarction, skeletal muscle and skin blood flow sufficient to prevent ischemic injury, and normal arterial pH (7.34 to 7.47) with a normal serum lactate concentration. Although these goals are achieved most often with a CI greater than 2.2 L/min/m^2, a mean arterial blood pressure greater than 60 mm Hg, and a PCWP of 15 mm Hg or greater, the absolute values are highly variable and depend on chronicity of illness, efficacy of chronic compensatory mechanisms, previous chronic therapy, and concurrent illnesses.

Discharge from the intensive care unit requires maintenance of the preceding parameters in the absence of ongoing intravenous infusion therapy, mechanical circulatory support, or positive-pressure ventilation. Some patients may achieve this goal with markedly lower blood pressure or higher filling pressure than suggested earlier; hence, numerical goals cannot always be substituted for clinical status. Nonpharmacologic treatments aimed at the precipitants of a patient's HF exacerbation include permanent pacing, chronic resynchronization therapy (also know as *biventricular pacing*) with or without an implantable cardioverter–defibrillator, coronary angioplasty or valvuloplasty, pericardial drainage, cardiac surgery (coronary bypass, valve replacement or reconstruction, closure of intracardiac shunts), or even cardiac transplantation, to achieve initial stabilization, definitive therapy, or both.

ABBREVIATIONS

ACC: American College of Cardiology

ACE: angiotensin-converting enzyme

ADHF: acute decompensated heart failure

AHA: American Heart Association

ANP: atrial natriuretic peptide

AVP: arginine vasopressin

BNP: B-type natriuretic peptide

cAMP: cyclic adenosine monophosphate

CI: cardiac index

CO: cardiac output

HFSA: Heart Failure Society of America

IABP: intraaortic balloon pump

LVAD: left ventricular assist device

NYHA: New York Heart Association

PCWP: pulmonary capillary wedge pressure

VAD: ventricular assist device

CHAPTER 23

Ischemic Heart Disease

ROBERT L. TALBERT

KEY CONCEPTS

1. Ischemic heart disease (IHD) is primarily caused by coronary atherosclerotic plaque formation that leads to an imbalance between oxygen supply and demand resulting in myocardial ischemia.
2. Chest pain is the cardinal symptom of myocardial ischemia due to coronary artery disease (CAD).
3. Risk factor identification and modification are important interventions for individual patients with known or suspected IHD and as a population-based policy to reduce the impact of this disease.
4. Major risk factors that can be altered include dyslipidemia (high total and LDL cholesterol, low HDL cholesterol, and high triglycerides), smoking, glycemic control in diabetes mellitus, hypertension, and adoption of therapeutic lifestyle changes (exercise, weight reduction, and reduced cholesterol and fat in the diet). Reduction in inflammation may also play an important role.
5. Most patients with CAD should receive antiplatelet therapy. Chronic stable angina should be managed initially with β-blockers because they provide better symptomatic control at least as well as nitrates or calcium channel blockers and decrease the risk of recurrent myocardial infarction (MI) and CAD mortality.
6. Nitroglycerin and other nitrate products are useful for prophylaxis of angina when patients are undertaking activities known to provoke angina; however, when angina is occurring on a regular, routine basis, chronic prophylactic therapy should be instituted.
7. Although calcium channel blockers are effective as monotherapy, they are generally used in combination with β-blockers or as monotherapy if patients are intolerant of β-blockers; most patients with moderate to severe angina will require two drugs to control their symptoms. Ranolazine is a second-line drug to be used with β-blockers and certain calcium channel blockers.
8. Pharmacologic management is as effective as revascularization (e.g., percutaneous transluminal coronary angioplasty [PTCA], coronary artery bypass grafting [CABG]) if one or two vessels are involved and there are no differences in survival, recurrent MI, or other measures of effectiveness.
9. Multivessel involvement, especially if the patient has left main CAD, left main equivalent disease, or two- to three-vessel involvement with significant left ventricular dysfunction, is best managed with revascularization. With improvements in stent technology, more patients are eligible for this approach compared to CABG.
10. PTCA and CABG produce similar results overall, but certain patient subsets (e.g., diabetics) should have CABG done.
11. The clinical performance measures for chronic stable CAD recommended by the American College of Cardiology and the American Heart Association include blood pressure measurement, lipid profile, symptom and activity assessment, smoking cessation, antiplatelet therapy, drug therapy for lowering LDL cholesterol, β-blocker therapy for prior MI, angiotensin-converting enzyme (ACE) inhibitor therapy, and screening for diabetes.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Ischemic heart disease (IHD) due to atherosclerosis of the epicardial vessels leading to coronary heart disease (CHD) is the main etiology of IHD. This process begins early in life, often not being clinically manifest until the middle-aged years and beyond. IHD may present as an acute coronary syndrome (ACS), which includes unstable angina, non–ST-segment elevation MI, or ST-segment elevation MI (see Chap. 24), chronic stable exertional angina pectoris, and ischemia without clinical symptoms. Coronary artery vasospasm (variant of Prinzmetal angina) produces similar symptoms but is not due to atherosclerosis. Microvascular angina, which is myocardial ischemia without occlusive CHD, is seen more commonly in women than men. Other manifestations of atherosclerosis include heart failure, arrhythmias, cerebrovascular disease (stroke), and peripheral vascular disease. The American Heart Association, the American College of Cardiology, and the European Society of Cardiology have published management guidelines for stable and unstable angina.[1–3]

EPIDEMIOLOGY

The American Heart Association (AHA) estimates that 81,100,000 American adults have one or more types of cardiovascular disease (CVD) based on data from 2003 through 2006.[4] Nearly 2,300 Americans die of CVD each day, or an average of 1 death every 38 seconds. In 2006, the death rates from CVD were 422.8 (per 100,000) for black males, 306.6 for white males, 298.2 for black females, and 215.5 for white females.[4] Mortality data for 2006 show that CVD accounted for 34.3% of 2,426,264 deaths in 2006 or 1 of every 2.9 deaths in the United States. Men die earlier from IHD and acute myocardial infarction (AMI) than women, and aging of

both sexes is associated with a higher incidence of these afflictions. The disparity in mortality from IHD between men and women decreases with aging, being about four to five times more common in men from the age of the mid-30s to a preponderance of female deaths in the very elderly.

The syndrome of angina pectoris is reported to occur with an average annual incidence rate (number of new cases per time period divided by the total number of persons in the population for the same time period) of about 1.5% (range 0.1 to 5/1000) depending on the patient's age, gender, and risk factor profile.[5] The presenting manifestation in women is more commonly angina, whereas men more frequently have MI as the initial event. Estimates of the incidence and prevalence of angina are not entirely accurate due to waxing and waning of symptoms; angina may disappear in up to 30% of patients with angina that is less severe and of recent onset.

Data from the Framingham study show that the prevalence in a 1970 cohort followed for 10 years was about 1.5% for women and 4.3% for men aged 50 to 59 years at inception.[5] The annual rate of new episodes of angina range from 28.3 to 33 per 1,000 population for nonblack men, 22.4 to 39.5 for black men, 14.1 to 22.9 for nonblack women, and 15.3 to 35.9 for black women in the age range of 65 to 84 years or older.[4] AHA estimates that the prevalence of angina was 10.2 million in 2006.[4] Between 1980 and 2002, death rates due to CHD among men and women ≥65 years of age fell by 52% in men and 49% in women.[4] The risk of developing IHD is not the same worldwide. Countries such as Japan and France are on the low end of the spectrum whereas Finland, Northern Ireland, Scotland, and South Africa have very high rates of IHD.[6,7]

Angina may be classified according to symptom severity, disability induced, or a specific activity scale (Tables 23–1 and 23–2). The specific activity scale developed by Goldman and coworkers[8] may be preferable because it has been shown to be equal to or better than the New York Heart Association or Canadian Cardiovascular Society functional classifications for reproducibility and provides better agreement with exercise treadmill testing.

An important determinate of outcome for the angina patient is the number of vessels obstructed. Twelve-year survival from the Coronary Artery Surgery Study (CASS) for patients with zero-, one-, two-, and three-vessel disease was 88%, 74%, 59%, and 40%, respectively.[9] Other factors that increase the risk of death in medically managed patients include the presence of heart failure (or markers such as poor ventricular wall motion and low ejection fraction), smoking, left main or left main–equivalent coronary artery disease (CAD), diabetes, or prior MI. Twelve-year survival for patients with at least one diseased vessel and ejection fractions in the ranges of ≥50%, 35% to 49%, and 0% to 34% is 73%, 54%, and 21%, respectively. Of particular note, patients with left main (or left main–equivalent) CAD are at extremely high risk and constitute a unique group for therapeutic consideration.[10] In the CASS, at 15 years of follow-up, 37% of the surgery group and 27% of the medical group are surviving; median survival is 13.3 years versus 6.7 years, respectively ($P<0.0001$). It is important to realize that these surgery studies are 15 years old and event rates are now likely lower. Technology advances in coronary artery stent development may now allow more patients to be treated with primary percutaneous intervention rather than coronary artery bypass grafting (CABG).[11] If systolic function was normal, then median survival and percent surviving were not different between the surgery and medical groups (median survival of about 15 years). Patients screened but not randomized to Coronary Artery Surgery Study (CASS) had similar survival rates, suggesting that results from randomized patients may be applicable to more generalized populations as a measure of external reliability.

TABLE 23-1 Criteria for Determination of the Specific Activity Scale Functional Class

	Any Yes	No
1. Can you walk down a flight of steps without stopping (4.5–5.2 MET[a])?	Go to 2	Go to 4
2. Can you carry anything up a flight of 8 steps without stopping (5–5.5 MET)? Or can you a. Have sexual intercourse without stopping (5–5.2 MET) b. Garden, rake, weed (5.6 MET) c. Roller skate, dance foxtrot (5–6 MET) d. Walk at a 4 miles/h rate on level ground (5–6 MET)	Go to 3	Class III
3. Can you carry at least 24 lb up 8 steps (10 MET)? Or can you a. Carry objects that weigh at least 80 lb (18 MET) b. Do outdoor work, shovel snow, spade soil (7 MET) c. Do recreational activities such as skiing, basketball, touch football, squash, handball (7–10 MET) d. Jog/walk 5 miles/h (9 MET)	Class I	Class II
4. Can you shower without stopping (3.6–4.2 MET)? Or can you a. Strip and make bed (3.9–5 MET) b. Mop floors (4.2 MET) c. Hang washed clothes (4.4 MET) d. Clean windows (3.7 MET) e. Walk 2.5 miles/h (3–3.5 MET) f. Bowl (3–4.4 MET) g. Play golf, walk and carry clubs (4.5 MET) h. Push a power lawnmower (4 MET)	Class III	Go to 5
5. Can you dress without stopping because of symptoms (2–2.3 MET)?	Class III	Class IV

ETIOLOGY AND PATHOPHYSIOLOGY

The pathophysiology that underlies this disease process is dynamic, evolutionary, and complex. An understanding of the determinants of myocardial oxygen demand (MVO_2), regulation of coronary blood flow, the effects of ischemia on the mechanical and metabolic function of the myocardium, and how ischemia is recognized are

TABLE 23-2 Grading of Angina Pectoris by the Canadian Cardiovascular Society Classification System

Class	Description of Stage
Class I	Ordinary physical activity does not cause angina, such as walking, climbing stairs. Angina occurs with strenuous, rapid, or prolonged exertion at work or recreation.
Class II	Slight limitation or ordinary activity. Angina occurs on walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals, or in cold, or in wind, or under emotional stress, or only during the few hours after wakening. Walking more than 2 blocks on the level and climbing more than 1 flight of ordinary stairs at a normal pace and in normal condition.
Class III	Marked limitations of ordinary physical activity. Angina occurs on walking 1 to 2 blocks on the level and climbing 1 flight of stairs in normal conditions and at a normal pace.
Class IV	Inability to carry on any physical activity without discomfort–anginal symptoms may be present at rest.

important in understanding the rationale for the selection and use of pharmacotherapy for IHD.

1 Ischemia may be defined as lack of oxygen and decreased or no blood flow in the myocardium. In contrast, anoxia, defined as the absence of oxygen to the myocardium, results in continued perfusion with washout of acid by-products of glycolysis, thereby preserving the mechanical and metabolic status of the heart to a greater extent than does ischemia for short periods of time.

DETERMINANTS OF OXYGEN DEMAND (MVO_2)

The major determinants of MVO_2 are (1) heart rate, (2) contractility, and (3) intramyocardial wall tension during systole. Overall, intramyocardial wall tension is thought to be the most important among these three factors. As the consequences of IHD are a result of increased demand in the face of a fixed supply of oxygen in most situations, alterations in MVO_2 are critically important in producing ischemia and for interventions intended to alleviate ischemia. MVO_2 can not be directly measured in patients; however, an indirect assessment that correlates reasonably well with MVO_2 as determined in experimental animal models is the tension–time index (TTI). This is a measure of the area under the curve of the left ventricular (LV) pressure curve. Tension in the ventricle wall is a function of the radius of the LV and intraventricular pressure. These factors are related through Laplace law, which states that wall stress is related directly to the product of intraventricular pressure and internal radius and inversely to wall thickness multiplied by a factor of 2. Increasing systemic blood pressure or ventricular dilation would increase wall tension and oxygen demand, whereas ventricular hypertrophy would tend to minimize increasing MVO_2. Clinical application of these principles has led to the use of the double product (DP), which is heart rate (HR) multiplied by systolic blood pressure (SBP) (DP = HR × SBP). Although this is a clinically useful indirect estimate of MVO_2, it does not consider changes in contractility (an independent variable), and because only changes in pressure are considered with the double product, volume loading of the LV and increased MVO_2 related to ventricular dilation are underestimated.

REGULATION OF CORONARY BLOOD FLOW

Coronary blood flow is influenced by multiple factors; however, the caliber of the resistance vessels delivering blood to the myocardium and MVO_2 are the prime determinants in the occurrence of ischemia. The anatomy of the vascular bed will affect oxygen supply and, subsequently, myocardial metabolism and mechanical function.

Anatomic Factors

The normal coronary system (see Fig. 23–1 for normal anatomy) consists of large epicardial or surface vessels (R1) that normally offer little intrinsic resistance to myocardial flow and intramyocardial arteries and arterioles (R2), which branch into a dense capillary network (about 4,000 capillaries/mm^2) to supply basal blood flow of 60 to 90 mL/min per 100 g of myocardium. R1 and R2 are in series and total resistance is the algebraic sum; however, under normal circumstances, the resistance in R2 is much greater. Myocardial blood flow is inversely related to arteriolar resistance and directly related to the coronary driving pressure. The arterioles dynamically alter their intrinsic tone in response to demands for oxygen and other factors, and as a result, myocardial oxygen delivery and myocardial oxygen demand are tightly coupled in a rapidly responsive system.

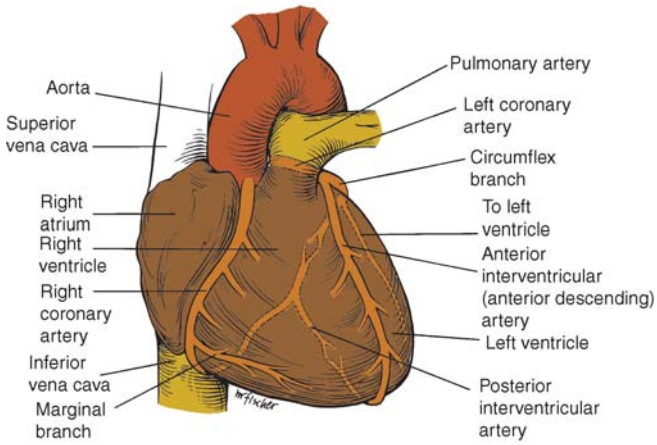

FIGURE 23-1. Coronary anatomy. *(From Tintinalli JE, Kelen GD, Stapczynski JR. Tintinalli's Emergency Medicine: A Comprehensive Study Guide, 6th ed. Copyright The McGraw Hill Companies, Inc. with permission. http://www.accessemergencymedicine.com.)*

Atherosclerotic lesions encroaching on the luminal cross-sectional area of the larger epicardial vessels (R1) transform the relationships among R1, R2, and blood flow. As resistance increases in R1 owing to occlusion, R2 can vasodilate to maintain coronary blood flow. This response is inadequate with greater degrees of obstruction, and the coronary flow reserve afforded by R2 vasodilation is insufficient to meet oxygen demand (also referred to as *autoregulation*). The extent of functional obstruction is important in the limitation of coronary blood flow, and the presence of relatively severe stenosis (>70%) may provoke ischemia and symptoms at rest, whereas less severe stenosis may allow a reserve of coronary blood flow for exertion.[12]

The diameter of the lesion impeding blood flow through a vessel is important, but other factors such as length of the lesion and the influence of pressure drop across an area of stenosis also affect coronary blood flow and function of the collateral circulation. Resistance to flow in a vessel is directly related to length of the obstructing lesion, but resistance is inversely related to the diameter of the vessel to the fourth power. Diameter is, therefore, much more important. As blood flows across a stenotic lesion, the pressure drops (energy losses) due to friction between blood and the lesion and to the abrupt turbulent expansion as blood emerges from the stenosis. This pressure drop is dynamic and directly related to flow giving rise to a resistance that is not fixed, but rather fluctuates, as flow is changed. This relationship can dramatically affect collateral blood flow and its response to exercise, resulting in what has been called *coronary steal*. A similar situation may also occur when the epicardial or subepicardial vessels "steal" blood flow from the endocardium in the presence of a stenotic lesion.

Large and small coronary arteries may undergo dynamic changes in coronary vascular resistance and coronary blood flow. Dynamic coronary obstruction can occur in normal vessels and vessels with stenosis in which vasomotion or spasm may be superimposed on a fixed stenosis. Although it is possible that these changes may be "active" in small coronary arteries, it is also possible that the observed changes may reflect collapse owing to poststenotic intraluminal pressure drop or increased intramyocardial compressive forces associated with inadequate ventricular relaxation.

Collateral blood flow exists to a certain extent from birth as native collaterals, but persisting ischemia may promote collateral growth as developed collaterals. These two types of collaterals differ in anatomy and in their ability to regulate coronary blood flow. Collateral development is dependent on the severity of obstruction,

the presence of various growth factors (basic fibroblast growth factor [β-FGF] and vascular endothelial growth factor [VEGF]), endogenous vasodilators (e.g., nitrous oxide, prostacyclin), hormones such as estrogen, and potentially exercise. Collateral development is highly species dependent, and this should be considered when reading experimental literature.

Metabolic Regulation

Coronary blood flow is closely tied to oxygen needs of the heart. Changes in oxygen balance lead to very rapid changes in coronary blood flow. Although a number of mediators may contribute to these changes, the most important ones are likely to be adenosine, other nucleotides, nitric oxide, prostaglandins, CO_2, and H^+. Adenosine, which is formed from adenosine triphosphate (ATP) and adenosine monophosphate (AMP) under conditions of ischemia and stress, is a potent vasodilator that links decreased perfusion to metabolically induced vasodilation or "reactive hyperemia." The synthesis and release of adenosine into coronary sinus venous effluent occurs within seconds after coronary artery occlusion, and about 30% of the hyperemic response can be blocked by metabolic blockers of adenosine. Coronary reactivity can be used to detect individuals at risk for future events.[13]

Endothelial Control of Coronary Vascular Tone

The vascular endothelium, a single-cell tissue with an enormous surface area separating the blood from vascular smooth muscle of the artery wall, is capable of a broad range of metabolic functions. The endothelium functions as a protective surface for the artery wall, and as long as it remains intact and functional, it promotes vascular smooth muscle relaxation and inhibits thrombogenesis and atherosclerotic plaque formation; damaged endothelium reacts to numerous stimuli with vasoconstriction, thrombosis, and plaque formation. The vascular endothelium of the coronary arteries synthesizes large molecules such as fibronectin, interleukin-1, tissue plasminogen activator, and various growth factors. Small molecules that are also produced include prostacyclin, platelet-activating factor, endothelin-1, and endothelium-derived relaxing factor (EDRF) that is now characterized as nitric oxide. EDRF is synthesized from l-arginine via nitric oxide synthase and released by shear force on the endothelium as well as through interaction with many biochemical stimuli such as acetylcholine, histamine, arginine, catecholamines, arachidonic acid, adenosine diphosphate (ADP), endothelin-1, bradykinin, serotonin, and thrombin. Nitric oxide then causes relaxation of the underlying smooth muscle and may be thought of as a paracrine homeopathic defense mechanism against noxious stimuli. Denudation or loss of the vascular endothelium results in loss of EDRF and this protective mechanism. Loss of the endothelial cell layer and function may occur secondary to physical disruption (percutaneous transluminal angioplasty [PTCA]), factors impinging from the vascular side (cyanide from smoke), or disruption of the intimal-medial layers (oxidized low-density lipoprotein). Impaired endothelial function may be related to the development of premature atherosclerosis based on recent family studies. Endothelial function may be improved with ACE inhibitors, statins, and exercise.[14]

Factors Extrinsic to the Vascular Bed

Blood flow to the coronary arteries arises from orifices located immediately distal to the aorta valve. Perfusion pressure is equal to the difference between the aortic pressure at an instantaneous point in time and the intramyocardial pressure. Coronary vascular resistance is influenced by phasic systolic compression of the vascular bed. The driving force for perfusion is, therefore, not constant throughout the cardiac cycle. Opening of the aortic valve may also lead to a Venturi effect, which can slightly decrease perfusion pressure. If perfusion pressure is elevated for a period of time, coronary vascular resistance declines and blood flow increases; however, continued perfusion pressure increases lead, within limits, to a return of coronary blood flow back toward baseline levels through autoregulation.

Alterations in intramyocardial wall tension throughout the cardiac cycle will also impose significant changes in coronary blood flow. Diastole is the period during which coronary artery filling can occur due to these pressure differences and little or no coronary blood flow occurs to the left ventricle during systole. The extent of pressure development in the ventricle and heart rate have a major effect on the development of wall tension, time for diastolic coronary artery filling, and myocardial oxygen demand.

Under normal conditions, the average global distribution of blood flow between the epicardial and endocardial layer is about 1:1 at rest and remains approximately even during exercise secondary to autoregulatory changes. Regional disparity of blood flow distribution does exist normally, and these disparities are magnified in the presence of diseased coronary arteries and with increased cardiac work as the vasodilator reserve in the resistance vessels of the subendocardial layers is exhausted. Factors that favor a reduction in subendocardial blood flow include decreased perfusion pressure due to decreased diastolic blood pressure or coronary artery obstruction by atherosclerotic plaques with or without vasomotion, abbreviation of diastole (increased heart rate), and increased intraventricular diastolic pressure (e.g., valvular obstruction to flow).

Extravascular resistance may decrease coronary blood flow, primarily during systole. This effect is much more pronounced in the left ventricle compared with the right ventricle (RV). When the effect of increased contractility is separated from the effect of ventricular pressure, about 75% of extravascular resistance is accounted for by passive stretch in equilibrium with ventricular pressure whereas only 25% results from active myocardial contraction.

Factors Intrinsic to the Vascular Bed

Metabolic factors, myogenic responses, neural reflexes, and humoral substances within the vascular bed of the coronary circulation function in an orchestrated fashion to maintain relative consistency in blood flow to the myocardium in the face of imposed changes in perfusion pressures. Autoregulation, mediated primarily through the effects of myogenic responses and metabolic factors, is thought to be responsible for maintaining regional blood flow in a narrow range while systemic pressure varies over a range of approximately 50 to 150 mm Hg.

Myogenic control (also known as the *Bayliss effect*) of coronary artery tone occurs when the vessel is stretched secondary to an increase in pressure and contracts to return blood flow to normal. It is thought that the myogenic response to stretching in coronary arteries is a modest one and that metabolic factors such as nitric oxide play a much larger role in autoregulation.

There are three well-studied metabolic factors that have the ability to modify coronary artery resistance and blood flow at the local level. Basal coronary blood flow meets oxygen demands of 8 to 10 mL/min per 100 g of myocardium with essentially complete extraction of oxygen from the blood. As cardiac output or mean arterial blood pressure increases, the increased demand for oxygen is met by increasing blood flow because little additional oxygen is available from hemoglobin. Decreased oxygen availability causes vasodilation of vascular smooth muscle and relaxation of precapillary sphincters, which increase tissue oxygen and help maintain blood flow on a regional basis.

At perfusion pressures below 60 mm Hg, as the coronary arteries are maximally dilated and the buffering effect of autoregulation has reached its capacity, further reduction in coronary blood flow will decrease perfusion pressure and tissue oxygenation. It is thought that autoregulation works more efficiently in the epicardial layers than in subendocardial layers, and this may contribute to coronary steal.

Neural components that participate in the regulation of coronary blood flow include the sympathetic nervous system, the parasympathetic nervous system, coronary reflexes, and possibly central control of coronary blood flow. Within the sympathetic system, stimulation of the stellate ganglion elicits coronary vasodilation, which is associated with tachycardia and enhanced contractility. This indirect coronary vasodilation is secondary to increased MVO_2 related to increased heart rate, contractility, and aortic pressure and occurs following stellate stimulation. The direct effect of the sympathetic system is α_1-mediated vasoconstriction at rest and during exercise. Other receptor types, α_2 and β_1, have little influence on tone, whereas β_2 stimulation produces a modest vasodilating effect. Although coronary atherosclerosis may decrease blood flow secondary to obstruction, severe coronary atherosclerosis and obstruction may also increase the sensitivity of coronary arteries to the effects of β1 stimulation and vasoconstriction.

Vagal stimulation within the parasympathetic system produces a small to moderate increase in coronary blood flow, which involves the coronary efferent and afferent parasympathetic components (Bezold–Jarish reflex). Indirectly, vasoconstriction may result, with vagal stimulation as the result of bradycardia and decreased contractility reducing myocardial oxygen demand.

Coronary reflexes have an undetermined role in the regulation of coronary blood flow. Based on experimental data, coronary reflexes that may be important include the baroreceptor, the chemoreceptor, Bezold–Jarish reflex, and the pulmonary inhalation reflex.

FACTORS LIMITING CORONARY PERFUSION

During exercise and pacing, as MVO_2 increases, coronary vascular resistance can be reduced to about 25% of basal values, which results in a fourfold to fivefold increase in coronary blood flow. The cross-sectional area can be reduced by about 80% prior to any mechanical or biochemical changes in the myocardium, reflecting a margin of safety for coronary blood flow. The extent of cross-sectional obstruction, the length of the lesion, lesion composition, and the geometry of the obstructing lesion can each affect flow across coronary arteries with atherosclerosis. Bernoulli's theorem states that the pressure drop across a lesion is directly related to the length of the lesion and inversely related to the radius of the lesion to the fourth power; critical stenosis occurs when the obstructing lesion encroaches on the luminal diameter and exceeds 70%. Lesions creating obstruction of 50% to 70% may reduce blood flow; however, these obstructions are not consistent and vasospasm and thrombosis superimposed on a "noncritical" lesion may lead to clinical events such as MI.[14] If the lesion enlarges from 80% to 90%, resistance in that vessel is tripled. Coronary reserve is diminished at about 85% obstruction owing to vasoconstriction. Exaggerated responsiveness can be seen when coronary stenosis reaches this critical level, and the role of vasoactive substances such as prostaglandins, thromboxanes, and serotonin may play more of a role in the regulation of coronary vascular tone and thrombosis.

Little reserve exists for coronary blood flow, and a relatively small reduction of 10% to 20% results in decreased myocardial fiber shortening as the first evidence for abnormal function. The subendocardial layers are affected to a greater extent than the epicardium by ischemia, considering changes in fiber shortening, arteriovenous (AV) difference in oxygen saturation, and lactate production. A reduction of 80% gives rise to akinesis and a 95% reduction of coronary blood flow produces dyskinesis during contraction of the ventricles. Although these abnormalities of contraction are associated with transient impaired function, depletion of high-energy phosphate compounds and ultrastructural changes may last for days even after transient ischemia; this has been referred to as *stunned myocardium*. Chronic hypoperfusion may lead to "hibernation," in which ventricular function is impaired over longer time intervals. Hibernating myocardium can be differentiated from necrosis with various techniques (see Chap. 17) and revascularization of hibernating myocardium is useful in improving ventricular function. Regional loss of contractility may impose a burden on the remaining myocardial tissue, resulting in heart failure, increased MVO_2, and rapid depletion of blood flow reserve. Consequently, zones of tissue with marginal blood flow may develop in a lateral or transmural fashion; such development puts this tissue at risk for more severe damage if the ischemic episode persists or becomes more severe. Nonischemic areas of myocardium may compensate for the severely ischemic and border zones of ischemia by developing more tension than usual in an attempt to maintain cardiac output. At the cellular level, ischemia and the attendant acidosis are thought to alter calcium release from storage sites such as the sarcolemma and the sarcoplasmic reticulum as well as inhibiting the binding of calcium to troponin, thereby impairing the association of actin and myosin. The clinical correlates of these cellular biochemical events leading to the development of LV or RV dysfunction include an S3, dyspnea, orthopnea, tachycardia, fluctuating blood pressure, transient murmurs, and mitral or tricuspid regurgitation.

Calcium accumulation and overload secondary to ischemia impairs ventricular relaxation as well as contraction. This is apparently a result of impaired calcium uptake after systole from the myofilaments, leading to a less negative decline of the pressure in the ventricle over time. Impaired relaxation is associated with enhanced diastolic stiffness, decreased rate of wall thinning, and slowed pressure decay, producing an upward shift in the ventricular pressure–volume relationship; put more simply, MVO_2 is likely to be increased secondary to increased wall tension. Impairment of both diastolic and systolic function leads to elevation of the filling pressure of the left ventricle.

CLINICAL PRESENTATION AND DIAGNOSIS OF ANGINA

General

- Many episodes of ischemia do not cause symptoms of angina (silent ischemia).
- Patients often have a reproducible pattern of pain or other symptoms that appear after a specific amount of exertion.
- Increased frequency, severity, duration, or symptoms at rest suggest an unstable angina pattern, and the patient should seek help immediately.

Symptoms

- 2 Sensation of pressure or burning over the sternum or near it, often but not always radiating to the left jaw, shoulder, and arm; also chest tightness and shortness of breath.
- Pain usually lasts from 0.5 to 30 minutes often with a visceral quality (deep location).
- Precipitating factors include exercise, cold environment, walking after a meal, emotional upset, fright, anger, and coitus.
- Relief occurs with rest and nitroglycerin.

Signs

- Abnormal precordial (over the heart) systolic bulge
- Abnormal heart sounds

Laboratory Tests

- Typically no laboratory tests are abnormal; however, if the patient has intermediate- to high-risk features for unstable angina, electrocardiographic changes and serum troponin, or creatine kinase, they may become abnormal (see Table 23-3).
- Patients are likely to have laboratory test abnormalities for the risk factors for IHD such as elevated total and LDL cholesterol, low HDL cholesterol, impaired fasting glucose or elevated glucose, high blood pressure, elevated C-reactive protein, and abnormal renal function. Hemoglobin should be checked to make sure the patient is not anemic.

Other Diagnostic Tests (See Chap. 17)

- A resting electrocardiogram and then an exercise tolerance test are usually the first tests done in stable patients. A chest x-ray should be done if the patient has heart failure symptoms. Cardiac imaging using radioisotopes to detect ischemic myocardium and to measure ventricular function are commonly done when revascularization is being considered. Echocardiography may also be used to assess ventricular wall motion at rest or during stress. Cardiac catheterization and coronary arteriography are used to determine coronary artery anatomy and whether the patient would benefit from angioplasty, coronary artery bypass surgery, or other revascularization procedures. Coronary artery calcium (CAC) may be useful in detecting early disease.

Important aspects of the clinical history for chest pain for patients with angina include the nature or quality of the pain, precipitating factors, duration, pain radiation, and the response to nitroglycerin or rest. Because there can be considerable variation in the manifestations of angina, it is more accurate to refer to these symptoms as an anginal syndrome. For some patients with significant coronary disease, their presenting symptoms may differ from the classical symptoms; yet the symptoms are due to ischemic pain, and these are often referred to as *anginal equivalents*. Obtaining an accurate and detailed family history is useful in placing symptoms in perspective. Significant positive information includes premature CHD (<55 years in men and <65 years in women) as manifested as fatal and nonfatal MI, stroke, peripheral vascular disease as well as other risk factors such as hypertension, smoking, familial lipid disorders, and diabetes mellitus (considered to be a risk equivalent). Typical pain radiation patterns include anterior chest pain (96%), left upper arm pain (83.7%), left lower arm pain (29.3%), and neck pain at some time (22%). Pain from other areas is less common. Ischemia detected by ECG monitoring is more likely to be detected in the morning hours (6 am to 12 noon) than other periods throughout the day. Patients suffering from variant or Prinzmetal angina secondary to coronary spasm are more likely to experience pain at rest and in the early morning hours. Prinzmetal anginal pain is not usually brought on by exertion or emotional stress nor relieved by rest; and the ECG pattern is that of current injury with ST elevation rather than depression. Typical pain that occurs in nonocclusive CAD is referred to as *microvascular angina*.

It is also important to differentiate the pattern of pain for stable angina from that of unstable angina. Unstable angina may be stratified into categories of risk ranging from high to low (Table 23–3).[15] Ischemia may also be painless, or "silent," in 60% to 100% of patients depending on the series cited and the patient population.[16] In patients with myocardial ischemia, approximately 70% of the episodes of documented ischemia are painless as determined by ambulatory ECG monitoring, and the ST segment changes associated with these episodes can be ST elevation or depression. The mechanism of silent ischemia is unclear, but studies have shown that patients not experiencing pain have altered pain perception, with the threshold and tolerance for pain being higher than that of patients who have pain more frequently. Although patients with diabetes tend to have more extensive and microvascular coronary disease than those without diabetes and may suffer from autonomic neuropathy, asymptomatic ischemia is not more prevalent based on the Asymptomatic Cardiac Ischemia Pilot (ACIP) study.[17]

Lastly, it should be recognized that the threshold for pain due to exertion is fixed for some patients and variable for others and that the amount of exercise or stress necessary to provoke symptoms can change over time. A fixed threshold for the induction of pain or ECG evidence of ischemia means these indicators of ischemia occur at the same, or nearly so, double rate–pressure product (systolic blood pressure × heart rate). This is apparently due to at least two factors. Over long periods of time atherosclerosis may progress, leading to more severe stenosis, reduced oxygen supply, and less

TABLE 23-3 Short-Term Risk of Death or Nonfatal Myocardial Infarction in Patients with Unstable Angina

Feature	High Risk (At Least 1 of the Following Features must be Present)	Intermediate Risk (No High-Risk Feature but must have 1 of the Following)	Low Risk (No High- or Intermediate-Risk Feature but may have any of the Following)
History	Accelerating tempo of ischemic symptoms in preceding 48 hours	Prior MI, peripheral or cerebrovascular disease, or CABG, prior aspirin use	New-onset CCS class III or IV angina in the past 2 weeks without prolonged (>20 minutes) rest pain but with moderate or high likelihood of CAD
Character of pain	Prolonged ongoing (>20 minutes), rest pain	Prolonged (>20 minutes), rest angina, now resolved, with moderate or high likelihood of CAD	
Clinical findings	Pulmonary edema, most likely caused by ischemia New or worsening MR murmur S_3 or new/worsening rales Hypotension, bradycardia, tachycardia Age >75 years		
ECG	Angina at rest with transient ST-segment changes >0.05 mV Bundle-branch block, new or presumed new	T-wave inversions >0.2 mV Pathologic Q waves	Normal or unchanged ECG during an episode of chest discomfort
Cardiac markers	Markedly elevated (e.g., TnT or TnI > 0.1 ng/mL)	Slightly elevated (e.g., TnT > 0.01 but <0.1 ng/mL)	Normal

CABG, coronary artery bypass grafting; CAD, coronary artery disease; CCS, Canadian Cardiovascular Society; ECG, electrocardiogram; MI, myocardial infarction; MR, mitral regurgitation; TnI, troponin; TnT, troponin T.

TABLE 23-4 Differential Diagnosis of Episodic Chest Pain Resembling Angina Pectoris

	Duration	Quality	Provocation	Relief	Location	Comment
Effort angina	5–15 minutes	Visceral (pressure)	During effort or emotion	Rest, NTG	Substernal, radiates	First episode vivid
Rest angina	5–15 minutes	Visceral (pressure)	Spontaneous (with exercise?)	NTG	Substernal, radiates	Often nocturnal
Mitral prolapse	Minutes to hours	Superficial (rarely visceral)	Spontaneous (no pattern)	Time	Left anterior	No pattern, variable
Esophageal reflux	10 minutes to 1 hour	Visceral	Spontaneous, cold liquids, exercise, lying down	Foods, antacids, H_2 blockers, proton pump inhibitors, NTG	Substernal, radiates	Mimics angina
Peptic ulcer	Hours	Visceral, burning	Lack of food, "acid" foods	Foods, antacids, H_2 blockers, proton pump inhibitors	Epigastric, substernal	
Biliary disease	Hours	Visceral (wax and wane)	Spontaneous, food	Time, analgesia	Epigastric, radiates	Colic
Cervical disk	Variable (gradually subsides)	Superficial	Spontaneous, food	Time, analgesia	Arm, neck	Not relieved by rest
Hyperventilation	2–3 minutes	Visceral	Emotion, tachypnea	Stimulus removed	Substernal	Facial paraesthesia
Musculoskeletal	Variable	Superficial	Movement, palpation	Time, analgesia	Multiple	Tenderness
Pulmonary	30 minutes	Visceral (pressure)	Often spontaneous	Rest, time bronchodilator	Substernal	Dyspneic

NTG, nitroglycerin.

of an increase in demand to precipitate ischemic symptoms. Once stenotic lesions reach a critical level of about 80% or greater, vasomotion, vasospasm, and thrombotic occlusion become significant factors impairing blood flow to the myocardium. Consequently, anatomic considerations and vasoactive substances may interact to provide an environment amenable to changing thresholds for the production of angina.

There appears to be little relationship between the historical features of angina and the severity or extent of coronary artery vessel involvement. Therefore, one may speculate that severe symptoms might be associated with multivessel disease, but no predictive markers exist on a routine basis.

Chest pain may resemble pain arising from a variety of noncardiac sources, and the differential diagnosis of anginal pain from other etiologies may be quite difficult based on history alone. Table 23–4 outlines other common problems that may present with episodic chest pain. Although much less common, nonatherosclerotic etiologies of CAD do exist and should be excluded with appropriate tests. The clinical classification of chest pain encompasses typical angina including (1) substernal chest pain with a characteristic quality and duration that is (2) provoked by exertion or emotional stress and (3) relieved by rest or nitroglycerin; atypical angina meets 2 of the characteristics for typical angina, and noncardiac chest pain meets ≤1 of the typical angina characteristics.[1,2]

There are few signs apparent on physical examination to indicate the presence of CAD and usually only the cardiovascular system reveals any useful information. Elevated heart rate or blood pressure can yield an increased double product and may be associated with angina, and it would be important to correct extreme tachycardia or hypertension if present. Other noncardiac physical findings that suggest that significant CVD may be associated with angina include abdominal aortic aneurysms or peripheral vascular disease. Cardiac examination findings in CAD are noted in Table 23–5. During an angina attack, these findings may appear or become more prominent, making them more valuable if present.

In addition to screening for CVD risk factors (Table 28–7), other recommended tests include hemoglobin, fasting glucose, fasting lipoprotein panel, resting ECG, and chest x-ray in patients with signs or symptoms of heart failure, valvular heart disease, pericardial disease or aortic dissection/aneurysm.[2] Hemoglobin is assessed to insure adequate oxygen carrying capacity. Fasting glucose determinations to exclude diabetes and glucose monitoring for concurrent diabetes should be performed routinely. Lipids are assessed total, LDL, and HDL cholesterol and triglycerides (see Chap. 28).[18] Other risk factors that may be important for some patients include C-reactive protein, homocysteine level, evidence of chlamydia infection, and elevations in lipoprotein(a), fibrinogen, and plasminogen

TABLE 23-5 Cardiac Findings for Patients with Coronary Artery Disease

Sign	Clinical Significance	Frequency
Abnormal precordial systolic bulge	Left ventricular wall motion abnormality	Not usually present unless patient has sustained a prior MI (especially anterior wall) or is experiencing angina at time of examination
Decreased intensity of S_1	Decrease in left ventricular contractility	Difficult to evaluate in resting state, but can be commonly demonstrated during angina
Paradoxical splitting of S_2	Left ventricular wall motion abnormality	Very uncommon but occasionally noted during angina
S_3 (ventricular gallop)	Increased left ventricular diastolic pressure, with or without clinical CHF	Not usually present unless patient sustained extensive MI; may occasionally be present during angina
S_4 (atrial gallop)	Reduced ventricular compliance ("stiff heart")	Common; very common in patients who have sustained a prior MI as well as during angina
Apical systolic murmur (in absence of rheumatic mitral regurgitation or Barlow syndrome)	Papillary muscle dysfunction	Not usually present unless patient has sustained prior MI
Diastolic murmur (in absence of aortic regurgitation)	Coronary artery stenosis	Rare

CHF, congestive heart failure; MI, myocardial infarction; S_1, first heart sound; S_2, second heart sound; S_3, third heart sound; S_4, fourth heart sound.

Clinical assessment (ACC/AHA, American College of Cardiologists/American Heart Association; AHCPR, Agency for Health Care Policy and Research; CABG, coronary artery bypass graft; ECG, electrocardiogram; LV, left ventricular; MI, myocardial infarction; PTCA, percutaneous transluminal coronary angioplasty).

activator inhibitor.[19] Cardiac enzymes should all be normal in stable angina. Troponin T or I, myoglobin or creatinine phosphokinase-MB isoform may be elevated in patients with unstable angina, and interventions such as anticoagulation or antiplatelet therapy have been shown to reduce cardiac end points when these markers for injury are elevated (Table 23–3).[20]

Patients presenting with chest pain are stratified into chronic stable angina or having features of intermediate or high-risk unstable angina (Fig. 23–2 and Table 23–3). These features include rest pain lasting >20 minutes, age >65 years, ST and T wave changes, and pulmonary edema. Patients with ACS (unstable angina, non-ST-segment elevation AMI and ST-segment elevation AMI) are managed differently than chronic stable angina.

DIAGNOSTIC TESTS

See also Chap. 17.

Electrocardiogram

The ECG is normal in about one half of patients with angina who are not experiencing an acute attack. Typical ST-T-wave changes include depression, T-wave inversion, and ST-segment elevation.

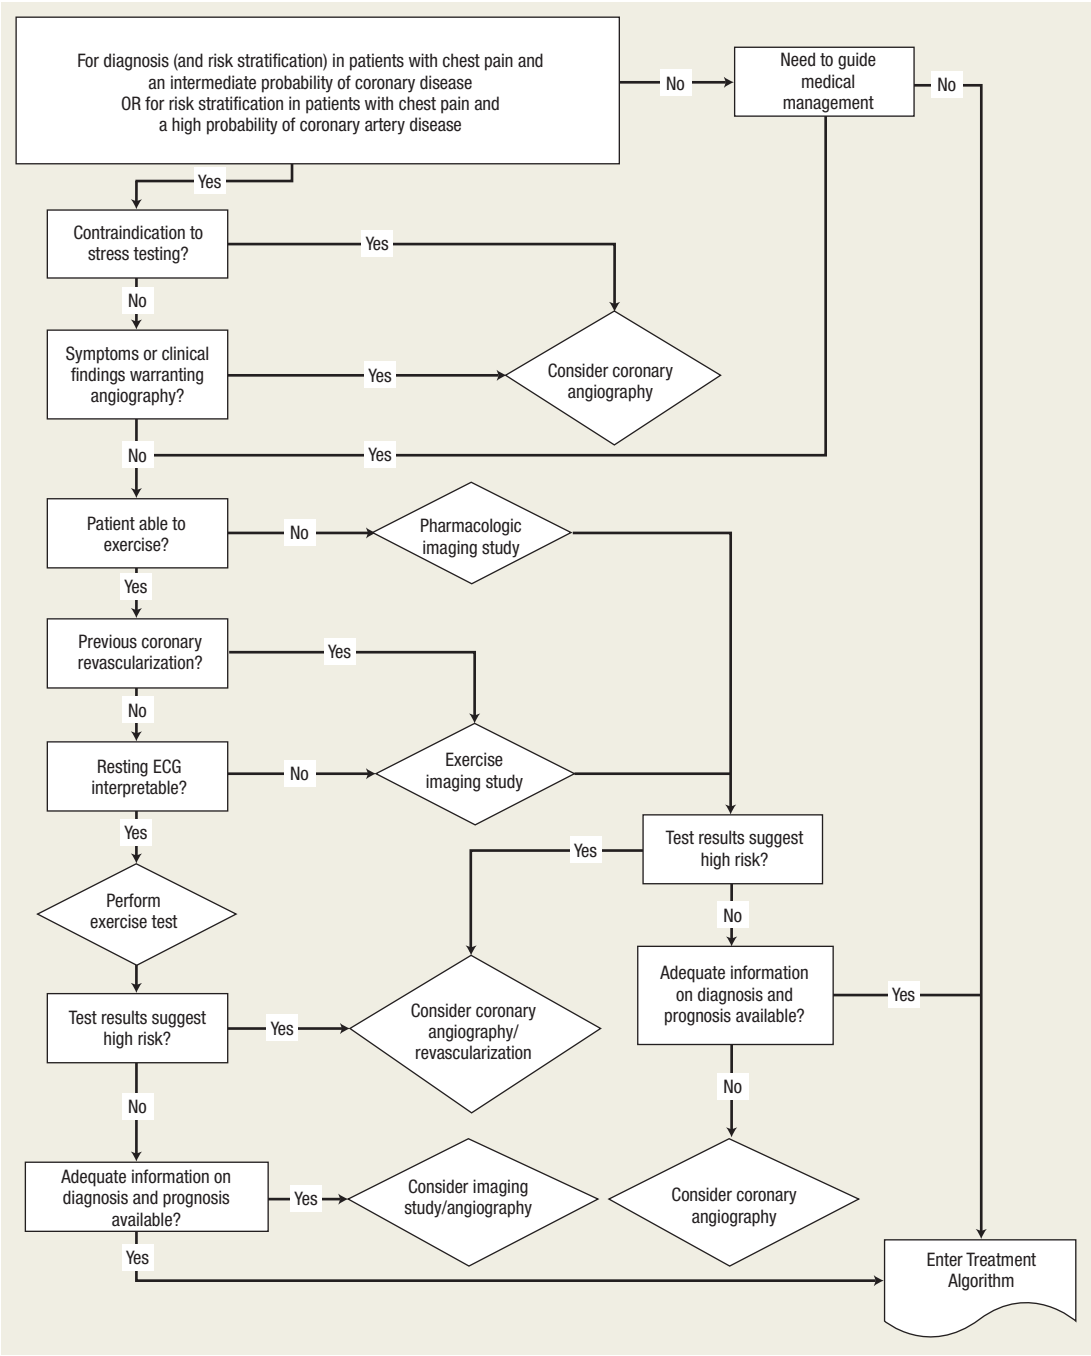

FIGURE 23-3. Stress testing/angiography algorithm. (ECG, electrocardiogram.)

Forms of ischemia other than exertional angina may have ECG manifestations that are different; variant angina is associated with ST-segment elevation, whereas silent ischemia may produce elevation or depression. Significant ischemia is associated with ST-segment depression of greater than 2 mm, exertional hypotension, and reduced exercise tolerance.

Exercise Tolerance Testing[21]

Exercise tolerance (stress) testing (ETT) is recommended for patients with intermediate pretest probability of CAD based on age, gender, and symptoms, including those with complete right bundle branch block or <1 mm of rest ST depression (Fig. 23–3). Although ETT is insensitive for predicting coronary artery anatomy, it does correlate well with outcomes such as the likelihood of progressing to angina, the occurrence of acute MI, and cardiovascular death. Ischemic ST depression that occurs during ETT is an independent risk factor for cardiac events and cardiovascular mortality. Thallium (^{201}Tl) myocardial perfusion scintigraphy may be used in conjunction with ETT to detect reversible and irreversible defects in blood flow to the myocardium because it is more sensitive than ETT.

Cardiac Imaging

Radionuclide angiocardiography (performed with technetium-99m, a radioisotope) is used to measure ejection fraction, regional ventricular performance, cardiac output, ventricular volumes, valvular regurgitation, asynchrony or wall motion abnormalities, and intracardiac shunts.[22–24] Technetium pyrophosphate scans

are used routinely for detection and quantification of AMI. Positron emission tomography (PET) is useful for quantifying ischemia with metabolically important substrates such as oxygen, carbon, and nitrogen. Other metabolic probes use radiolabeled fatty acids and glucose to study metabolic processes that may be deranged during ischemia in animals and for investigative purposes in man.

A new method using ultra-rapid computerized tomography (spiral CT, ultrafast CT, electron beam CT) minimized artifact due to motion of the heart during contraction and relaxation and provides a semiquantitative assessment of calcium content in coronary arteries.[22] The overall sensitivity of 95% and specificity of 66% for coronary calcium score to predict obstructive disease on invasive angiography.

Echocardiography

Echocardiography is useful if patients have history or physical examination suggestive of valvular, pericardial disease or ventricular dysfunction. For patients unable to exercise, pharmacologic stress echocardiography (dobutamine, dipyridamole, or adenosine) or pacing may be done to identify abnormalities during stress.

Cardiac Catheterization and Coronary Arteriography

Cardiac catheterization and angiography for patients with suspected CAD are used diagnostically to document the presence and severity of disease as well as for prognostic purposes. High-risk features during ETT suggesting the need for coronary angiography include early and significant (≥2 mm) changes on the ECG during ETT as well as multiple lead involvement, prolonged recovery from ischemia, low workload performance, abnormal blood pressure response (reduction in blood pressure), or ventricular arrhythmias. Multiple defects with thallium scans as well as lung uptake during exercise or postexercise ventricular cavity dilation are also high-risk indications for catheterization. Interventional catheterization is used for thrombolytic therapy for patients with AMI and for the management of patients with significant CAD to relieve obstruction through PTCA, atherectomy, laser treatment, or stent placement. Catheterization and angiography may be done after CABG to determine if the graft has closed or if CAD has progressed. Coronary artery intravascular ultrasound (IVUS) is useful for directly imaging anatomy, calcified and fatty plaques, and thrombosis superimposed on plaque as well as determining patency following revascularization procedures. IVUS guidance of stent implantation may result in more effective stent expansion compared with angiographic guidance alone.[23]

TREATMENT

Desired Outcome

The short-term goals of therapy for IHD are to reduce or prevent the symptoms of angina that limit exercise capability and impair quality of life. Long-term goals of therapy are to prevent CHD events such as MI, arrhythmias, and heart failure and extend the patient's life. Since there is little evidence that revascularization procedures such as angioplasty and coronary artery bypass surgery extend life, the primary focus should be on altering the underlying and ongoing process of atherosclerosis through risk factor modification while providing symptomatic relief through the use of nitrates, β-blockers, calcium channel blockers and ranolazine for anginal symptoms.

Risk Factor Modification

3 Primary prevention of IHD through the identification and modification of risk factors prior to the initial morbid event would be the optimal management approach and should result in a significant impact on the prevalence of IHD. However, early recognition of some risk factors may not be possible in all cases, and in others, the patient may not be willing to undertake intervention until overt evidence of coronary disease is apparent. Secondary intervention continues to be more commonly pursued by both healthcare professionals and patients, and it is important to recognize this type of intervention as effective in reducing subsequent morbidity and mortality. The presence of risk factors in individual patients plays a major role in determining the occurrence and severity of IHD.[24,25] Risk factors are additive in nature and can be classified as alterable or unalterable (see Table 28-7). Unalterable risk factors include gender; age; family history or genetic composition; environmental influences such as climate, air pollution, trace metal composition of drinking water; and, to some extent, diabetes mellitus. Improved glycemic control reduces the microvascular complications of diabetes mellitus (see Chap. 83); however, with publication of the ACCORD trial strict control of glucose did not improve the primary outcome.[26] 4 Risk factors that can be altered include smoking, hypertension, dyslipidemia, obesity, sedentary lifestyle, hyperuricemia, psychosocial factors such as stress and type A behavior patterns, and the use of certain drugs that may be detrimental including progestins, corticosteroids, and calcineurin inhibitors.

Cigarette smoking is common. The Center for Disease Control and Prevention estimates that ~46 million people are current smokers (23.1% men; 18.3% women) in this country, and the risk for CHD is increased by about 1.8 in active smokers and by about 1.3 for passive or environmental smoke exposure.[4] Each year 443,000 Americans die from smoking-related illnesses and 142,000 of the deaths are attributable to CVD.[4] Risk due to smoking is related to the number of cigarettes smoked per day and the duration of smoking. Passive smoking in angina pectoris patients has been shown to decrease exercise time.[6] Pipe and cigar smokers are at increased risk compared with nonsmokers, but their risk is somewhat less than that of cigarette smokers.[27] The direct effects of cigarette smoke that are detrimental to patients with angina include the following:

1. Elevated heart rate and blood pressure from nicotine, which increases MVO_2, and impaired myocardial oxygen delivery due to carboxyhemoglobin generation from carbon monoxide inhalation in smoke
2. The negative inotropic effect of carboxyhemoglobin
3. Increased platelet adhesiveness and promotion of aggregation resulting in thrombotic tendencies due to nicotine and carboxyhemoglobin
4. Lowered threshold for ventricular fibrillation during ischemia due to carboxyhemoglobin
5. Impaired endothelial function owing to smoking[28–31]

Similar changes have been noted for marijuana smoking as well. Smoking also accelerates the risk for MI, sudden death, cerebrovascular disease, peripheral vascular disease, and hypertension, and it reduces high-density lipoprotein concentrations. Clearly, primary prevention is needed for this risk factor and much of the education effort to discourage initiation of smoking should be targeted for teenagers. Techniques for cessation of smoking that may be useful include aversive conditioning, group programs, self-help programs, hypnosis, "cold turkey," and the use of nicotine substitutes (lobeline) or other sources of nicotine replacement products

for short-term substitution during withdrawal syndrome. The antidepressant sustained-release bupropion has been shown to be more effective than placebo and best used with smoking cessation counseling. Varenicline, a partial agonist selective for the α_4 β_2 nicotinic acetylcholine receptor subtype has been shown to improve cessation rates as well.[28,29] Cessation of smoking reduces the incidence of coronary events to about 15% to 25% of that associated with continued smoking and these benefits are noted within 2 years of cessation.[30] A public ordinance reducing exposure to secondhand smoke was associated with a decrease in AMI hospitalizations in Pueblo, Colorado by 27% in 2 years.[31]

Hypertension, whether labile or fixed, borderline or definite, casual or basal, systolic or diastolic, at any age regardless of gender, is the most common and a powerful contributor to atherosclerotic coronary vascular disease.[32] Morbidity and mortality increase progressively with the degree of blood pressure elevation of either systolic or diastolic pressure and pulse pressure, and no discernible critical value exists (see Chap. 19). Numerous trials have documented the reduction in risk associated with blood pressure lowering; however, most of these studies show that mortality and morbidity reduction is a result of fewer strokes and less renal failure and heart failure. The reduction in CHD end points is significant but not as dramatic. The reasons for this are unclear but perhaps relate to the multifactorial etiology of IHD. Recent guideline changes from the AHA recommend goal blood pressure of <130/80 mmHg for patients with stable angina, unstable angina, non–ST-segment MI, and ST-segment MI and <120/80 mmHg for patients with LV dysfunction.[32]

Hypercholesterolemia is a significant cardiovascular risk factor, and risk is directly related to the degree of cholesterol elevation.[24,33] As with hypertension, there is no critical value that defines risk, but rather, risk is incrementally related to the degree of elevation and the presence of other risk factors (see Chap. 28 for a detailed discussion). A fasting lipoprotein panel should be obtained in all patients with known CAD. The goals for total, LDL, and HDL cholesterol and triglycerides are discussed in Chap. 28. All patients should undertake therapeutic lifestyle changes. Reductions in LDL cholesterol for primary prevention and secondary intervention have been shown to reduce total and CAD mortality and stroke as well as the need for interventions such as PTCA and CABG. Supplemental vitamin E or other antioxidants reduce the susceptibility of LDL cholesterol to oxidation, but clinical trial data have failed to show any benefit with supplementation.[34]

The prevalence of overweightness and obesity, defined as a *body mass index* (BMI)—weight in kg divided by height in meters squared—of ≥25 kg/m^2 and ≥30 kg/m^2, respectively, are estimated to occur in 66.3% and 34.3% of the U.S. population. BMI is associated with an increased mortality ratio compared with individuals of normal body weight, and the objective for patients with IHD is to maintain or reduce to a normal body weight.[4] This may be accomplished through dietary modification, exercise, pharmacologic therapy, or surgical therapy. Frequently associated with obesity is a sedentary lifestyle, and inactivity may contribute to higher blood pressure, elevated blood lipid levels, and insulin resistance associated with glucose intolerance in diabetics (insulin resistance or metabolic syndrome). Exercise to the level of about 300 kcal 3 times/week is useful in improving maximal oxygen uptake, improving cardiorespiratory efficiency, promoting collateral artery formation, and promoting potential alterations in the risk of ventricular fibrillation, coronary thrombosis, and improved tolerance to stress. Epidemiologic studies have found that mortality is directly related to resting heart rate and a low heart rate difference between resting and maximal exercise heart rate and inversely related to exercise heart rate. A regular exercise program has been shown to reduce all-cause and cardiac mortality.[35,36]

Competitiveness, intense striving for achievement, easily provoked hostility, a sense of urgency about doing things quickly and being punctual, impatience, abrupt and rapid speech and gestures, and concentration on self-selected goals to the point of not perceiving and attending to other aspects of the environment are traits that characterize the behavioral pattern known as the type A or coronary prone personality. Although the issue is somewhat controversial, type A individuals may have increased cardiovascular risk with risk ratios ranging from insignificant to 3 times that of a matched population. Psychological stress and type D personality have been associated with adverse cardiac prognosis, but little is known about their relative effect on the pathogenesis of CHD. *Type D* refers to the tendency to experience negative emotions and to inhibit the expression of these emotions in social interactions. The mechanism by which personality affects the cardiovascular system is not understood but may reflect the activity of the sympathetic system and enhanced responsiveness of other stress hormones when compared with non-type A personalities.

Alcohol ingestion in small to moderate amounts (<40 g/d of pure ethanol) reduces the risk of CHD; however, consumption of large amounts (>50 g/d) or binge drinking of alcohol is associated with increased mortality from stroke, cancer, vehicular accidents, and cirrhosis.[37,38] There appears to be a differential effect depending on race with an inverse relationship between ethanol consumption in whites and CAD risk but a direct relationship in blacks between consumption and CAD risk. The mechanisms for the presumed protective effects of alcohol are not known but the effects may be related to increased high-density lipoprotein levels, impaired platelet function, or associations between the amount of alcohol ingested and personality type. Whatever the relationship, it is well to remember that alcohol drinking is implicated in over 40% of all fatal automobile accidents and consumption of alcohol predisposes to hepatic cirrhosis, the sixth to seventh most common cause of death of the middle aged in the United States. With this in mind, it seems illogical to suggest alcohol ingestion as a prophylactic measure for coronary disease but rather advise moderation of alcohol consumption, if it is the preference of the individual.

Thiazide diuretics have been shown to elevate serum cholesterol and triglyceride levels, whereas β-blockers tend to lower HDL and raise LDL slightly; however, a direct association between these drugs and cardiovascular risk is tenuous and based on aggregating results rather than randomized clinical trials. Conjugated equine estrogen alone or in combination with progestin lowers LDL and raises HDL; unfortunately, the Heart and estrogen/progestin replacement study (HERS) trial showed no benefit of hormone replacement therapy for secondary intervention and increased risk for thromboembolism.[39] In secondary intervention, hormone replacement therapy (HRT) or estrogen alone in women after hysterectomy found that hormonal therapy health risks exceeded benefits as well.[40] Unopposed estrogen is the optimal regimen for elevation of HDL, but the high rate of endometrial hyperplasia restricts use to women without a uterus. In women with a uterus, estrogen with cyclic medroxyprogesterone has the most favorable effect on HDL and no excess risk of endometrial hyperplasia. Use of oral contraceptives in women who smoke and are over the age of 35 years increases the risk of MI, stroke, and venous thromboembolism by threefold or higher. Alternative forms of contraception and cessation of smoking should be promoted for these patients. The risk for nonsmoking oral contraceptive users under the age of 35 is very small. The relative risk of breast cancer is increased, but in the absence of risk factors for breast cancer, the relative risk is approximately 1.3 (30% increase). Coffee consumption has also been linked to CHD and caffeine does transiently elevate blood pressure; however, the overall risk, if any, appears to be low and may be related to genetic makeup (cytochrome P450 (CYP)

TABLE 23-6 The American College of Cardiology and American Heart Association Evidence Grading System

Recommendation Class	
I	Conditions for which there is evidence or general agreement that a given procedure or treatment is useful and effective
II	Conditions for which there is conflicting evidence or a divergence of opinion that the usefulness/efficacy of a given procedure or treatment is useful and effective
IIa	Weight of evidence/opinion is in favor or usefulness/efficacy
IIb	Usefulness/efficacy is less well established by evidence/opinion
III	Conditions for which there is evidence or general agreement that a given procedure or treatment is not useful/effective and in some cases may be harmful

Level of Evidence	
A	Data derived from multiple randomized clinical trials with large numbers of patients
B	Data derived from a limited number of randomized trials with small numbers of patients, careful analyses of nonrandomized studies, or observational registries
C	Expert consensus was the primary basis for the recommendation

1A2 mutation).[41] Although thiazide diuretics and β-blockers (nonselective without intrinsic sympathomimetic activity) may elevate both cholesterol and triglycerides by some 10% to 20%, and these effects may be detrimental, no objective evidence exists from prospective well-controlled studies to support avoiding these drugs at this time. This controversy is most pertinent in the treatment of mild hypertension, and it is discussed in greater detail in Chap. 19.

TREATMENT

Stable Exertional Angina Pectoris

(Table 23–6 contains evidence grading recommendations.)

The current national guidelines recommend that all patients be given the following unless contraindications exist:

1. Aspirin (Class I, Level A);
2. β-blockers with prior MI (Class I, Level A)
3. ACE inhibitor to patients with CAD and diabetes or LF systolic dysfunction (Class I, Level A)
4. LDL-lowering therapy with CAD and LDL >130 mg/dL (Class I, Level A) (target LDL <100 mg/dL; <70 mg/dL for patients with CHD and multiple risk factors is reasonable)[33]
5. SL nitroglycerin or immediate relief of angina (Class I, Level B)
6. Calcium antagonists or long-acting nitrates for reduction of symptoms when β-blockers are contraindicated (Class I, Level B)
7. Calcium antagonists or long-acting nitrates in combination with β-blockers when initial treatment with β-blockers is not successful (Class I, Level C)
8. Calcium antagonists or long-acting nitrates are recommended as a substitute for β-blockers if initial treatment with β-blockers leads to unacceptable side effects (Class I, Level A).

Clopidogrel may be substituted when aspirin is absolutely contraindicated (Class IIa, Level B) and long-acting non-dihydropyridine calcium antagonists instead of β-blockers as initial therapy (Class IIa, Level B). ACE inhibitors are recommended for patients with CAD or other vascular disease (Class IIa, Level B). Angiotensin receptor antagonists are not mentioned in these guidelines, but substitution for ACE inhibitor intolerance is reasonable. Low-intensity anticoagulation with warfarin, in addition to aspirin, is recommended, but bleeding would be increased (Class IIb, Level B).[1,42]

Therapies to be avoided include dipyridamole (Class III, Level B) and chelation therapy (Class III, Level B). Ranolazine is not addressed in these guidelines because it was released after their publication. The European Society of Cardiology guidelines have a Class IIb, Level B recommendation.[3]

After assessing and manipulating the alterable risk factors as discussed previously, the next intervention that could be undertaken is the institution of a regular exercise program. Training is possible in many patients with angina and the observed benefits include decreased heart rate and systolic blood pressure as well as increased ejection fraction and duration of exercise. Although the mechanism of these effects has been debated, improved overall cardiovascular and muscular condition is probably most important. Improved production of nitric oxide and coronary vasomotion may account partially for the beneficial effects of exercise. The intensity of exercise influences training and more vigorous programs provide better overall results.[35,36] Obviously, an exercise program should be undertaken with caution and in a graded fashion with adequate supervision.

5 Chronic prophylactic therapy for patients with more than one angina episode per day may also be instituted with β-adrenergic blocking agents, and in many instances β-blockers may be preferable because of less frequent dosing and other properties inherent in β-blockade (e.g., potential cardioprotective effects, antiarrhythmic effects, lack of tolerance, and antihypertensive effects), as well as their antianginal effects and documented protective effects in post-MI patients.[1,42] β-Blockers may also slow the progression of plaque volume.[43]Patients who continue to smoke have reduced antianginal efficacy of β-blockers. This may be due to enhanced hepatic metabolism of drugs that are eliminated through this route or related to the effects of smoking on MVO_2 and oxygenation.[44] The one characteristic that is relevant is the duration of effect on the double product. β-Blockers with longer half-lives (e.g., nadolol) are more likely to affect the double product for a longer period of time and require fewer doses per day. The choice of β-blocker for angina rests on choosing the appropriate dose to achieve the goals outlined for heart rate and double product and choosing an agent that is well tolerated by individual patients and cost. Selective use may incorporate ancillary properties, but these are secondary considerations in overall drug product selection. Patients most likely to respond well to β-blockade are those who have a high resting heart rate and those having a relatively fixed anginal threshold. In other words, their symptoms appear at the same level of exercise or workload on a consistent basis. Symptoms appearing with variable workloads suggest fluctuations in myocardial oxygen supply, perhaps due to coronary artery vasomotion, and these patients are more likely to respond to calcium channel antagonists.

6 Nitrate therapy should be the first step in managing acute attacks for patients with chronic stable angina if the attacks are infrequent (i.e., a few times per month) or for prophylaxis of symptoms when undertaking activities known to precipitate attacks. In general, if angina occurs no more often than once every few days, then sublingual (SL) nitroglycerin tablets or spray or buccal products may be sufficient to allow the patient to maintain an

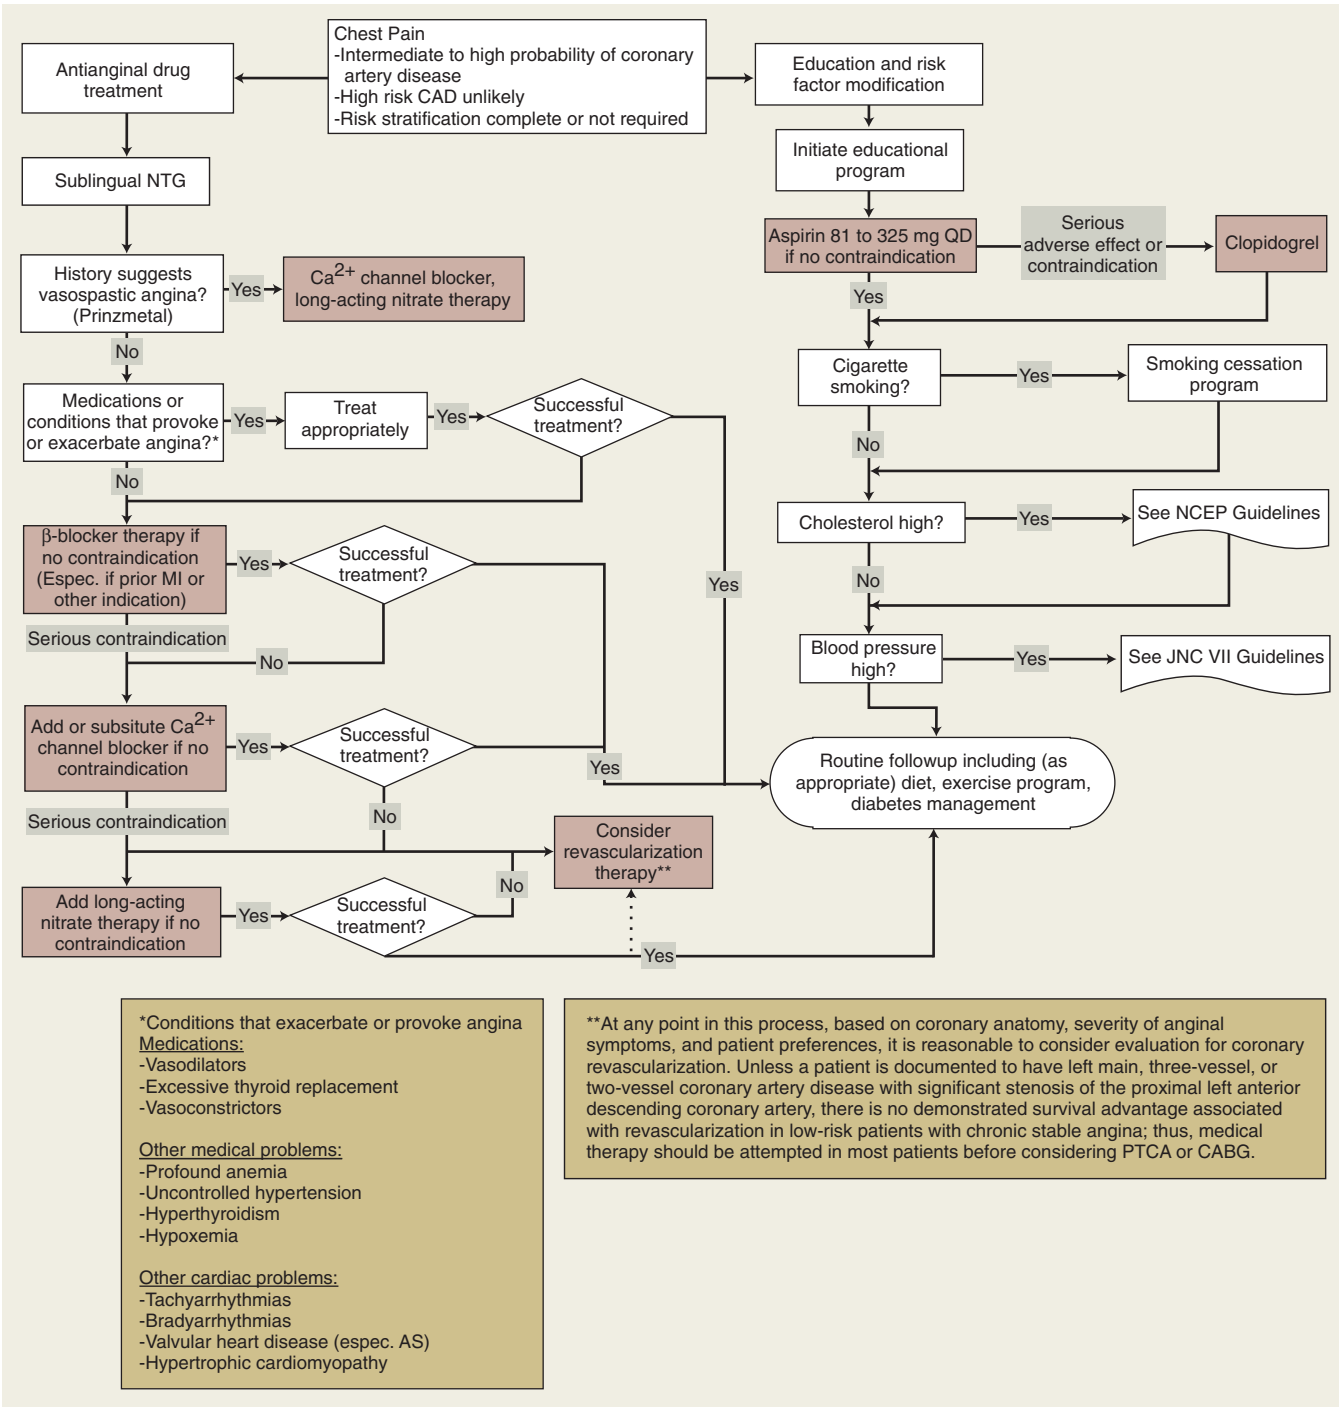

FIGURE 23-4. Treatment algorithm (AS, aortic stenosis; CABG, coronary artery bypass grafting; CAD, coronary artery disease; JNC VII, Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure; MI, myocardial infarction; NCEP, National Cholesterol Education Program; NTG, nitroglycerin; PTCA, percutaneous transluminal coronary angioplasty; QD, every day.)

adequate lifestyle. For episodes of "first-effort" angina occurring in a predictable fashion, nitroglycerin may be used in a prophylactic manner with the patient taking 0.3 to 0.4 mg sublingually about 5 minutes prior to the anticipated time of activity. Nitroglycerin spray may be useful when inadequate saliva is produced to rapidly dissolve SL nitroglycerin or if a patient has difficulty opening the container. Most patients have a response that lasts about 30 minutes or so, but this is subject to interindividual variability. When angina occurs more frequently than once a day, a chronic prophylactic regimen using β-blockers as the first line of therapy should be considered (see Fig. 23–4 for the stable angina algorithm). Chronic prophylactic therapy with long-acting forms of nitroglycerin (oral or transdermal), isosorbide dinitrate, 5-mononitrate, and pentaerythritol trinitrate may be effective; however, the development of tolerance is a major limiting step in their continued effectiveness. Since long-acting nitrates are not as effective as β-blockers and do not have beneficial effects, monotherapy with nitrates should not be first-line therapy unless β-blockers and calcium channel blockers are contraindicated or not tolerated. As described previously, providing a nitrate-free interval of 8 hours per day or longer appears to be the most promising approach to maintaining the efficacy of chronic nitrate therapy. Recent investigations into the

mechanisms of nitrate tolerance have shown in normal volunteers that treatment with isosorbide mononitrate for 7 days resulted in tolerance but also endothelial dysfunction which is thought to be due to reactive oxygen species generated during bioactivation of high-potency nitrates.[45,46] Chronic nitrate use may be associated with ACS presentation changes with a preponderance of unstable angina and NSTEMI over STEMI.[47] Oral administration of nitrates is susceptible to a saturable first-pass effect; therefore, larger doses can produce a measurable hemodynamic effect and dose titration should be based on these changes in the double product. There are few well-controlled studies comparing oral or SL nitrate efficacy, and the choice among these products should be based on familiarity with the preparation, cost, and patient acceptance.

7 Calcium channel antagonists have the potential advantage of improving coronary blood flow through coronary artery vasodilation as well as decreasing MVO_2 and may be used instead of β-blockers for chronic prophylactic therapy; however, in chronic stable angina comparative trials of long-acting calcium channel blockers with β-blockers do not show significant differences in response.[48,49] They are as effective as β-blockers and are most useful for patients who have a variable threshold for exertional angina. Calcium antagonists may provide better skeletal muscle oxygenation, resulting in decreased fatigue and better exercise tolerance. Additionally, if contraindications exist to β-blocker therapy, calcium antagonists can be safely used in many patients. The available calcium channel blockers appear to have similar efficacy in the management of chronic stable angina. Differences in their electrophysiology, peripheral and central hemodynamic effects, and adverse effect profiles are useful in selecting the appropriate agent. Patients with conduction abnormalities and moderate to severe LV dysfunction (ejection fraction <35%) should not be treated with verapamil or diltiazem, whereas amlodipine may be safely used in many of these patients. Diltiazem has significant effects on the AV node and can produce heart block for patients with preexisting conduction disease or when other drugs, such as digoxin or β-blockers, with effects on conduction are used concurrently. Nifedipine may cause excessive heart rate elevation, especially if the patient is not receiving a β-blocker, and this may offset the beneficial effect it has on MVO_2. Gingival hyperplasia has also been reported with nifedipine, and some dental authorities say this may be seen in as many as 20% of patients on nifedipine. Case control studies with calcium blockers suggest an increased risk for MI and cancer.[50,51] The relationship to cancer appears to be weak to nonexistent, whereas the risk for MI is probably real and related to the type of drug used and relationship to recent MI. Immediate release formulations of calcium blockers can activate the sympathetic nervous system and for patients with recent MI or significant coronary disease may induce ischemia. This effect has not been shown for longer acting products. The hemodynamic effect of calcium antagonists is complementary to β-blockade, and consequently, combination therapy is rational, but clinical trial data do not support the notion that combination therapy is always more effective.[48,52]

While revascularization (see the following section) would seem to provide better symptomatic relief and improved survival rates, recent randomized trials have shown no advantage of angioplasty or surgery over medical therapy for patients with stable CAD. In the Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial the 4.6-year cumulative primary-event rates (death from any cause and nonfatal MI) were 19.0% in the PCI group and 18.5% in the medical-therapy group (hazard ratio for the PCI group, 1.05; 95% confidence interval [CI], 0.87 to 1.27; $P = 0.62$).[53,54] Medicine, Angioplasty, or Surgery Study (MASS II) found medical therapy was associated with an incidence of long-term events and rate of additional revascularization similar to those for PCI. CABG was superior to medical therapy in terms of the primary end points, reaching a significant 44% reduction in primary end points at the 5-year follow-up of patients with stable multivessel CAD.[55]

TABLE 23-7 Recommended Mode of Coronary Revascularization

Extent of Disease	Treatment	Class/Level of Evidence
Left main disease,[a] candidate for CABG	CABG	I/A
	PCI	III/C
Left main disease, not a candidate for CABG	PCI	IIb/C
Three-vessel disease with EF <0.50	CABG	I/A
Multivessel disease including proximal LAD with EF <0.50 or treated diabetes	CABG	I/A
	PCI	IIb/B
Multivessel disease with EF >0.50 and without diabetes	PCI	I/A
One- or two-vessel disease without proximal LAD but with large areas of myocardial ischemia or high-risk criteria on noninvasive testing (see text)	CABG or PCI	I/B
One-vessel disease with proximal LAD	CBAG or PCI	IIa/B
One-or two-vessel disease without proximal LAD with small area of ischemia or no ischemia on noninvasive testing	CABG or PCI	III/C
Insignificant coronary stenosis	CABG or PCI	III/C

CABG, coronary artery bypass grafting; EF, ejection fraction; LAD, left anterior descending coronary artery; PCI, percutaneous coronary intervention.
[a]Less than 50% diameter stenosis.

8 NONPHARMACOLOGIC THERAPY

Revascularization

The decision to undertake PCI or CABG for revascularization is based on the extent of coronary disease (number of vessels and location and/or amount of stenosis) and ventricular function. The recommended mode of coronary revascularization is outlined in Table 23–7.[56,57]

The largest randomized trial of PCI versus CABG is the Bypass Angioplasty Revascularization (BARI) trial conducted in 1,829 patients with two- or three-vessel disease; 64% of these patients had an admitting diagnosis of UA and 19% were diabetic.[58] The 10-year survival was 71.0% for PTCA and 73.5% for CABG ($P = 0.18$). At 10 years, the PTCA group had substantially higher subsequent revascularization rates than the CABG group (76.8% vs 20.3%, $P<0.001$), but angina rates for the two groups were similar. In the subgroup of patients with no treated diabetes, survival rates were nearly identical by randomization (PTCA 77.0% vs CABG 77.3%, $P = 0.59$).[59] Insulin-requiring diabetics and chronic kidney disease seem to be at the highest risk, and CABG is the revascularization procedure of choice for this population.[54] In a large observational study by Hannan et al., patients with proximal LAD lesions and multivessel disease had higher survival rates with CABG than with PTCA.[58,60,61] High-risk patients who should be considered for CABG over PCI are those with LV systolic dysfunction, patients with diabetes, and those with two-vessel disease with severe proximal LAD involvement or severe three-vessel or left main disease[56] (Table 23–7). Angina with Extremely Serious Operative Mortality (AWESOME) found that patients who were older than 70 years of age support the trial conclusions that either bypass or percutaneous intervention

effectively relieves medically refractory ischemia among high-risk unstable angina patients whose age was >70 years.[62]

PCI has been used successfully in the management of unstable angina.[63] PTCA involves the insertion of a guidewire and inflatable balloon into the affected coronary artery and enlarging the lumen of the artery by stretching the vessel wall. This frequently causes atheroma plaque fracture by stretching inelastic components and denudation of the endothelium resulting in loss of nitric oxide and other vasodilators and exposure of plaque contents to the vascular compartment. Consequently, immediate vascular recoil, platelet adhesion and aggregation, mural thrombus formation, smooth muscle proliferation, and synthesis of extracellular matrix may give rise to acute occlusion and early or late restenosis.[64–66] The presence of coronary artery spasm and intraluminal thrombus, common occurrences in unstable angina, increases the hazard of these complications. The advent of combination therapy with Aspirin (ASA), Unfractonated Heparin (UFH), or Low Molecular Weight Heparin LMWH) and IIb/IIIa receptor antagonists and coronary artery stents has dramatically reduced the occurrence of early reocclusion and late restenosis.[67,68] Patients best suited for PTCA are those with recent onset of worsening of angina without a long history of symptoms. Angiographic characteristics associated with these clinical findings that allow the greatest probability of success for PTCA are severe, discrete, proximal lesions found in a large epicardial vessel subtending a moderate or large area of viable myocardium and have high risk. Patients with focal saphenous-vein-graft lesions who are poor candidates for reoperation have a Class IIa recommendation for PCI. Class IIb indications include patients with one or more lesions to be dilated in vessels subtending a less than moderate area of viable myocardium and patients with multivessel disease and proximal LAD lesions, diabetes, or abnormal LV function.[57] Previously, candidates for PTCA must also be suited for CABG because a small percentage of procedures results in emergency CABG. Improvements in PCI and stent technology have lead to some institutions performing procedures without surgical backup.[69] Success of PCI may be defined as angiographic success (TIMI 3 flow and <20% residual stenosis), procedural success (lack of in-hospital clinical complications), and clinical success (anatomic and procedural success with relief of ischemic pain for at least 6 months). In trials of invasive versus conservative strategies (medical management) using PCI, death or MI is less frequent in some trials but not all.[53,70,71] Numerous studies support the use of IIb/IIIa receptor antagonists in addition to ASA and UFH or LMWH and as described previously, abciximab was superior to tirofiban in the only comparative study available.[72,73] The initial success rate for PTCA in unstable angina is ~80% to 90%, but these patients are at risk for more complications than are those with stable angina because of the underlying pathophysiology.

In the event of prolonged chest pain and ischemic ECG changes unrelieved by nitrate therapy or calcium channel antagonists, one may assume total occlusion of a coronary vessel and steps should be taken to restore blood flow with either PCI or CABG.

Coronary Artery Bypass Grafting[74]

Following the introduction of saphenous-vein-graft replacement for the severely occluded coronary arteries by Favorolo and Garrett in 1967, CABG became an accepted and commonly used approach for the management of IHD. The objectives in performing CABG are twofold: (1) reduce the number of symptomatic anginal attacks not controlled with medical management or PCI and improve the lifestyle of the patient and (2) reduce the mortality associated with CAD. Surgery is effective in providing pain relief in large numbers of patients, with about 70% to 95% being pain free at 1 year and 46% to 55% being pain free at 5 years. This compares favorably with medical management, for which only about 30% are free of symptoms at 5 years. Mortality at 10 years from the largest published studies is 26.4% with CABG and 30.5% with medical management ($P = 0.03$), but there are significant differences based on subgroup analysis (e.g., left main disease vs one-vessel without a proximal LAD lesion).[74] The second objective is met for certain patients and this has been addressed in three large, well-controlled trials of bypass surgery. These three studies, the Veterans Administration (VA), European Cooperative Surgery Study (ECSS), and the CASS, are not directly comparable because the inclusion and exclusion criteria for entry into each study were different and patients were followed for different periods of time. They have also been criticized for not being representative of the population that may be candidates for surgery, lacking women or late-middle-aged or elderly patients, and for crossover of medically managed patients to the surgical group. A major change in medical practice that influences the interpretation of these older studies is the common procedure of stent placement at the time of angioplasty.[11,75] There are about 20 different types of stents available, and their use is associated with greater luminal diameter after angioplasty, fewer acute reocclusions, and less restenosis after stent placement.[76] Consequently, the validity of generalizing the results from these studies to routine practice has been questioned, but these studies are useful for providing a basis for decisions concerning surgery. Current class I recommendations for CABG in asymptomatic or mild angina patient includes significant (>50%) left main coronary artery stenosis, left main equivalent (≥70% stenosis of the proximal LAD and proximal left circumflex artery), and three-vessel disease, especially for patients with LV ejection fraction <0.50.[74] Class IIa recommendations for CABG are proximal LAD stenosis with one- or two-vessel disease and Class IIb one- or two-vessel disease not involving the proximal LAD. In stable angina, Class I recommendations are the same as for mild angina with the following additions: one- or two-vessel disease without significant proximal LAD stenosis, but with a large area of viable myocardium and high-risk criteria in noninvasive testing; disabling angina despite maximal medical therapy, when surgery can be performed with acceptable risk. Class IIb recommendations in stable angina include proximal LAD stenosis with one-vessel disease and one- or two-vessel disease without significant proximal LAD stenosis but with a moderate area of viable myocardium and ischemia on noninvasive testing. The indications for CABG in UA/NSTEMI are described previously. In ST-segment MI CABG is indicated for ongoing ischemia/infarction not responsive to maximal medical therapy (Class IIb).

For patients with poor LV function CABG is indicated for the same indications as in mild angina for Class I. Class IIa recommendations include poor LV function with significant viable, noncontracting, revascularizable myocardium without any of the aforementioned anatomic patterns (e.g., left main disease). CABG is useful for patients with life-threatening ventricular arrhythmia in the presence of left main disease, three-vessel disease (Class I) and in bypassable one- or two-vessel disease causing life-threatening ventricular arrhythmias and proximal LAD disease with one- or two-vessel disease (Class IIa).

CABG may also be used for patients who have failed PTCA if there is ongoing ischemia or threatened occlusion with significant myocardium at risk and for patients with hemodynamic compromise (Class I). Class IIa recommendations for failed PTCA include a foreign body in a crucial anatomic position and hemodynamic compromise for patient with impairment of the coagulation system and without a previous sternotomy. CABG may be repeated for patients with a previous CABG if disabling angina exists despite maximal noninvasive therapy (Class I) and if a large area of myocardium is threatened and is subtended by bypassable distal vessels (Class IIa).

The need for nitrates and β-blockers is clearly reduced by surgery, with only 30% of CABG patients requiring chronic medication, whereas 70% of their medical counterparts received anginal drugs. Employment status after surgery has been shown in CASS to be more dependent on the pretreatment status than an effect induced by the treatment arm, and about 70% of patients are employed before and after surgery. Recent follow-up analyses of these studies suggest that patients who have diabetes or peripheral vascular disease, who are African American, or who continued to smoke are at high risk for CAD events, and diabetics, in particular, are more likely to have a better outcome with CABG than PTCA.[58,70] The overall benefit noted after CABG is similar in men and women, and elderly patients appear to have outcomes similar to younger patients.

Operative mortality is reported to range from 1% to 3% and is related to the number of vessels involved and preoperative ventricular function. Patients in CASS with one-, two-, or three-vessel disease had operative mortalities of 1.4%, 2.1%, and 2.8%, respectively. The relationship to LV ejection fraction follows a similar trend with ejection fractions of >50%, 20% to 40%, and <20% having operative mortality rates of 1.9%, 4.4%, and 6.7%, respectively. Perioperative infarction averages 5% depending on the sensitivity of the method for assessment, and the occurrence of an infarct reduces long-term survival. Neurologic dysfunction is relatively common postoperatively in CABG patients (~6%), but many of the deficits are clinically insignificant and resolve with time. Fatal brain damage occurs in 0.3% to 0.7%, stroke in about 5%, and ophthalmologic defects occur in 25%, but only 3% have clinically apparent field defects. Peripheral nerve lesions (12%) and brachial plexopathy (7%) are also reported to occur. Other complications include constrictive pericarditis (0.2%), cellulitis at the site of vein graft, and mediastinal infections (1% to 4%).

Graft patency influences the success for symptom control, and survival and the mechanism for early graft occlusion are probably different from that associated with late closure. Early occlusion is related to platelet adhesion and aggregation, whereas late occlusion may be related to endothelial proliferation and progression of atherosclerosis. Patency of grafts early on after the CABG is reported to range from 88% to 97% in at least one graft and 58% to 81% in all grafts at 1 year. Long-term patency based on the CASS Montreal Heart Institute experience suggests that 60% to 67% of all grafts remain patent at 5 to 11 years. Antiplatelet therapy has been demonstrated to improve early and late patency rates and should probably be used for all patients who do not have any contraindications.[72,73,77] Aspirin with or without other antiplatelet agents reduces the late development of vein-graft occlusions. At the current time, prasugrel, a new antiplatelet drug is only indicated for patients with ACS who are going to undergo PCI.[78] Late graft closure is related to elevated lipid levels and the progression of atherosclerosis in the grafted vessels as well as the native circulation. Elevation of very low density lipoprotein (VLDL), low-density lipoprotein (LDL), and LDL apolipoprotein B is correlated to disease progression and graft closure. Aggressive lipid lowering can stabilize the progression of CAD and may induce regression in selected coronary artery segments within a patient following CABG. Cessation of smoking is an important preoperative and postoperative objective as well as in the management of other coronary risk factors (e.g., hypertension), and institution of a supervised, daily exercise program is recommended. Internal mammary artery grafts should be used for revascularizing the left anterior descending artery system when possible due to better graft survival and clinical outcomes.

Valvular heart disease can coexist with CHD, although this is relatively uncommon with rheumatic valve disease, usually the mitral valve, and more common with aortic stenosis and regurgitation. Angina may occur in 35% to 65% of patients with aortic stenosis or regurgitation and, if severe, may be the cause of angina in the absence of CAD. Patients being evaluated for possible CABG should also be evaluated for valvular disease to determine if valve replacement needs to be performed along with bypass grafting.

Percutaneous Transluminal Coronary Angioplasty[63]

Since the introduction into clinical cardiology of PTCA by Gruentzig in 1977, this procedure has gained rapid acceptance as a safe and effective means of managing CAD. It is estimated that more than 750,000 PCI procedures are done each year in this country and 525,000 of them are PTCA. The proposed mechanisms of reduced stenosis with PTCA include (1) compression and redistribution of the atherosclerotic plaque, (2) embolization of plaque contents, (3) aneurysm formation, and (4) disruption of the plaque and arterial wall with distortion and tearing of the intima and media, which leads to denudation of the endothelium, platelet adhesion and aggregation, thrombus formation, and smooth muscle proliferation. Of these mechanisms, mechanism (4) is felt to be the most important, but the others may contribute to opening of the lesions in some situations.

9 The indications for PTCA have been provided by the ACC/AHA and now span single- or multivessel disease as well as asymptomatic and symptomatic patients (see Table 23–8).[63] In addition to providing recommendations for which type of patients are appropriate for PTCA, the guidelines also provide recommendations for the volume of procedures, the use of IVUS and surgery backup when PTCA is being considered. 10 PTCA generally is not useful if only a small area of viable myocardium is at risk, when ischemia cannot be demonstrated, when borderline (<50%) stenosis or lesions are difficult to dilate, or when patients are at high risk for morbidity or mortality or both (e.g., left main or equivalent disease or three-vessel disease). PTCA alone or when used sequentially or in conjunction with thrombolysis for AMI is discussed in Chap. 18. Stent placement accompanies balloon angioplasty in about 80% of cases in the United States. The current recommendations for PCI are provided in Table 23–8 based on class of angina.

Assessment of outcome with PCI can be based on several angiographic, procedural and clinical outcomes as discussed previously. The success of PCI is dependent on the experience of the operator (high volume, better outcome), complicating factors for the patient (including the number of vessels to be dilated), and technical advances in the equipment used (e.g., steerable and low-profile catheters). The acute success rate for opening of uncomplicated stenotic lesions ranges from 96% to 99% with the combined balloon–device–pharmacologic approach in experienced hands, and angina is decreased or eliminated in about 80% of cases. The success rate for totally occluded lesions is somewhat less (~65%). Mortality at 1 year is 1% and 2.5% for single-vessel disease and multiple-vessel involvement, respectively, reflecting the good prognosis associated with this degree of CAD. At 10 years, survival is 95% and 81% for single and multiple disease, respectively.[63] Most patients remain event free (no death, MI, or CABG) for an extended period. Symptomatic status, as measured by the New York Heart Association (NYHA) classification, is improved in many patients. Restenosis is noted in 32% to 40% after balloon angioplasty at 6 months, and half of these patients will have symptoms associated with restenosis.[63] A few late restenotic events occur, but most restenosis occurs within the first 6 months. Anatomic factors that predict restenosis include lesions >20 mm in length, excessive tortuosity of the proximal segment, extremely angulated segments (>90°), total occlusions >3 months old and and/or bridging collaterals, and the inability to protect

TABLE 23-8 Percutaneous Coronary Intervention Based on Angina Class

Patients with Asymptomatic Ischemia or Canadian Cardiovascular Society (CCS) Class I or II Angina		
Class I Patients who do not have treated diabetes with asymptomatic ischemia or mild angina with 1 or more significant lesions in 1 or 2 coronary arteries suitable for PCI with a high likelihood of success and low risk of morbidity and mortality. The vessels to be dilated must subtend a large area of viable myocardium. (Level of Evidence: B)	**Class IIa** 1. PCI is reasonable in patients with asymptomatic ischemia or CCS class I or II angina and with 1 or more significant lesions in 1 or 2 coronary arteries suitable for PCI with a high likelihood of success and a low risk of morbidity and mortality. The vessels to be dilated must subtend a moderate to large area of viable myocardium or be associated with a moderate to severe degree of ischemia on noninvasive testing. (Level of Evidence: B)	Phrasing has been changed to reflect current terminology. The recommendation and all of those that follow in Section 5 have been reworded to be consistent with the CCS classification system of angina. This recommendation has been changed to class IIa to reflect the published data and Writing Committee consensus that not all patients in this clinical category must have PCI performed.
Class IIa 1. The same clinical and anatomic requirements as for class I, except the myocardial area at risk is of moderate size or the patient has treated diabetes. (Level of Evidence: B)		This recommendation has been merged with other class IIa recommendations of this section, and the phrasing has been changed to reflect current terminology.
	2. PCI is reasonable for patients with asymptomatic ischemia or CCS class I or II angina, and recurrent stenosis after PCI with a large area of viable myocardium or high-risk criteria on noninvasive testing. (Level of Evidence: C)	This is a new recommendation dealing with the management of recurrent stenosis after PCI among patients with asymptomatic ischemia or class I or II angina.
	3. Use of PCI is reasonable for patients with symptomatic ischemia or CCS class I or II angina with significant left main CAD (>50% diameter stenosis) who are candidates for revascularization but are not eligible for CABG. (Level of Evidence: B)	This recommendation for PCI among patients who are eligible for CABG who have significant left main disease has been added to reflect the favorable results noted by several trials with PCI.
Class IIb Patients with asymptomatic ischemia or mild angina with greater than or equal to 3 coronary arteries suitable for PCI with a high likelihood of success and a low risk of morbidity and mortality. The vessels to be dilated must subtend at least a moderate area of viable myocardium. In the physician's judgment, there should be evidence of myocardial ischemia by ECG exercise testing, stress nuclear imaging, stress echocardiography or ambulatory ECG monitoring, or intracoronary physiologic measurements. (Level of Evidence: B)		This recommendation has been eliminated and replaced by the following 2 recommendations. For each, the phrasing has been constructed to reflect current terminology.
	Class IIb 1. The effectiveness of PCI for patients with asymptomatic ischemia or CCS class I or II angina who have two- or three- vessel disease with significant proximal LAD CAD who are otherwise eligible for CABG with 1 arterial conduit and who have treated diabetes or abnormal LV function is not well established. (Level of Evidence: B)	Phrasing has been changed to reflect current terminology. Among patients who are eligible, CABG with 1 arterial conduit is generally preferred for treatment of multivessel disease with significant proximal LAD obstruction in patients with treated diabetes and/or abnormal OV function.
	2. PCI might be considered for patients with asymptomatic ischemia or CCS class I or II angina with nonproximal LAD CAD that subtends a moderate area of viable myocardium and demonstrates ischemia on noninvasive testing. (Level of Evidence: C)	Phrasing has been changed to reflect current terminology. PCI might be considered in this clinical setting.
Class III Patients with asymptomatic ischemia or mild angina who do not meet the criteria as listed under class I or class II and who have a. Only a small area of viable myocardium at risk b. No objective evidence of ischemia c. Lesions that have a low likelihood of successful dilation d. Mild symptoms that are unlikely to be due to myocardial ischemia e. Factors associated with increased risk of morbidity or mortality f. Left main disease g. Insignificant disease <50% (Level of Evidence: C)	**Class III** PCI is not recommended for patients with asymptomatic ischemia or CCS class I or II angina who do not meet the criteria as listed under the class II recommendations or who have 1 or more of the following: a. Only a small area of viable myocardium at risk (Level of Evidence: C) b. No objective evidence of ischemia (Level of Evidence: C) c. Lesions that have a low likelihood of successful dilation (Level of Evidence: C) d. Mild symptoms that are unlikely to be due to myocardial ischemia (Level of Evidence: C) e. Factors associated with increased risk of morbidity or mortality (Level of Evidence: C) f. Left main disease and eligibility for CABG (Level of Evidence: C) g. Insignificant disease (<50% coronary stenosis) (Level of Evidence: C)	

(continued)

TABLE 23-8 Percutaneous Coronary Intervention Based on Angina Class (continued)

Patients with CCS Class III Angina		
Class I	**Class IIa**	
Patient with 1 or more significant lesions in 1 or more coronary arteries suitable for PCI with a high likelihood of success and low risk of morbidity or mortality. The vessel(s) to be dilated must subtend a moderate or large area of viable myocardium and high risk. (Level of Evidence: B)	1. It is reasonable that PCI be performed in patients with CCS class III angina and single-vessel or multivessel CAD who are undergoing medical therapy and who have 1 or more significant lesions in 1 or more coronary arteries suitable for PCI with a high likelihood of success and low risk of morbidity or mortality. (Level of Evidence: B)	Phrasing has been changed to reflect current terminology. Recommendation has been reworded to be consistent with CCS classification system for angina. The recommendation class has been changed to IIa to reflect published data and Writing Committee consensus. Criteria regarding viable and high-risk myocardium have been deleted from this commendation.
Class IIa		
Patients with focal saphenous vein graft lesions or multiple stenoses that are poor candidates for reoperative surgery. (Level of Evidence: C)	2. It is reasonable that PCI be performed in patients with CCS class III angina with single-vessel or multivessel CAD who are undergoing medical therapy with focal saphenous vein graft lesions or multiple stenoses who are poor candidates for reoperative surgery. (Level of Evidence: C)	Phrasing has been changed to reflect current terminology.
	3. Use of PCI is reasonable in patients with CCS class III angina with significant left main CAD (>50% diameter stenosis) who are candidates for revascularization but are not eligible for CABG. (Level of Evidence: B)	This recommendation for PCI among patients with significant left main disease who are not eligible for CABG has been added to reflect the favorable results noted by several trials with PCI.
Class IIb	**Class IIb**	
Patient has 1 or more lesions to be dilated with reduced likelihood of success of the vessel(s) subtend a less than moderate area of viable myocardium. Patients with two- or three-vessel disease, with significant proximal LAD CAD and treated diabetes or abnormal LV function. (Level of Evidence: B)	1. PCI may be considered in patients with CCS class III angina with single-vessel or multivessel CAD who are undergoing medical therapy and who have 1 or more lesions to be dilated with a reduced likelihood of success. (Level of Evidence: B)	Phrasing has been changed to reflect current terminology. The 2001 recommendation has been split into 2 separate recommendations.
	2. PCI may be considered in patients with CCS class III angina and no evidence of ischemia on noninvasive testing or who are undergoing medical therapy and have two- or three-vessel CAD with significant proximal LAD CAD and treated diabetes or abnormal LV function. (Level of Evidence: B)	Phrasing has been changed to reflect current terminology. The use of noninvasive testing to evaluate for evidence of ischemia has been added.
Class III	**Class III**	
Patient has no evidence of myocardial injury or ischemia on objective testing and has not had a trial of medical therapy, or has a. Only a small area of myocardium at risk b. All lesions or the culprit lesion to be dilated with morphology with a low likelihood of success c. A high risk of procedure-related morbidity or mortality. (Level of Evidence: C)	PCI is not recommended for patients with CCS class III angina with single-vessel or multivessel CAD, no evidence of myocardial injury or ischemia on objective testing, and no trial of medical therapy, or who have 1 of the following: a. Only a small area of myocardium at risk (Level of Evidence: C) b. All lesions or the culprit lesion to be dilated with morphology that conveys a low likelihood of success (Level of Evidence: C) c. A high risk of procedure-related morbidity or mortality (Level of Evidence: C) d. Insignificant disease (<50% coronary stenosis) (Level of Evidence: C) e. Significant left main CAD and candidacy for CABG (Level of Evidence: C)	Phrasing has been changed to reflect current terminology. Class II recommendations two and three from the 2001 guidelines have been merged into this recommendation.
2. Patients with insignificant coronary stenosis (e.g., <50% diameter). (Level of Evidence: C) 3. Patients with significant left main CAD who are candidates for CABG. (Level of Evidence: B)		

CAEBG, coronary artery bypass graft; CAD, coronary artery disease; ECG, electrocardiography; LAD, left anterior descending; LV, left ventricle; OV, outflow volume; PCI, percutaneous coronary intervention.

major side branches and degenerated vein grafts with friable lesions. Clinical factors that predict worse outcome include diabetes, advanced age, female gender, unstable angina, heart failure, and multivessel disease. A 4-variable scoring system that predicts cardiovascular collapse for failed PTCA includes percentage of myocardium at risk (e.g., >50% viable myocardium at risk and LV ejection fraction <25%), preangioplasty percent diameter stenosis, multivessel CAD, and diffuse disease in the dilated segment or a high myocardial jeopardy score.[63] Strut thickness of the stent influences restenosis as well, and thicker struts are associated with angiographic and clinical restenosis.[76,79] With the development of drug-eluting stents (DES), early reocclusion has been reduced dramatically, but late in-stent thrombosis has been a problem. As stent technology has evolved better polymers, better strut design, and better antiproliferative agents (e.g., everolimus), stent thrombosis has dropped to as low as 0.3%, MI to 1.9%, and target-lesion revascularization to 2.5%.[76]

The overall complication rate ranges from 2% to 21% depending on the lesion type. Coronary occlusion, dissection, or spasm occurs in 4% to 8% of patients, whereas ST-segment-elevation MI occurs

in 1.6% to 4.8%.[63] Prolonged angina and ventricular tachycardia or fibrillation occurs in 6.9% and 2.3%, respectively. In-hospital mortality ranges from 0.7% to 2.5% overall, and high-risk events for mortality included ventricular arrhythmias and MI. The frequency of urgent CABG because of complications ranges from 0.4% to 5.8%.[63]

Current AHA/ACC recommendations for antithrombotic therapy in PCI are outlined in Table 23–9.[63,77] Antiplatelet therapy with ASA 80 to 325 mg/day given at least 2 hours prior to angioplasty is currently recommended. If patients are sensitive to ASA, clopidogrel or prasugrel are acceptable alternatives. In elective settings, clopidogrel should be started at least 72 hours in advance of the procedure to allow for maximal antiplatelet effects. Alternatively, a loading dose of clopidogrel (300 to 600 mg) or prasugrel 60 mg may be given to achieve a more rapid antiplatelet effect.[80–82] The combination of ASA plus clopidogrel or prasugrel is currently recommended for patients undergoing angioplasty and stenting, and this combination is safer and superior to antiplatelet therapy plus anticoagulation with warfarin-like drugs.[77] Follow-up for up to 4 years from the Intracoronary Stenting and Antithrombotic Regimen (ISAR) trial shows that the benefit of combined antiplatelet therapy evident after 30 days is maintained after 4 years.[83] Aspirin is an incomplete inhibitor of platelet aggregation and combination therapy of ASA plus a GP IIb/IIIa receptor antagonist for PCI has shown a relative risk reduction of 37.5% for death and nonfatal MI at 30 days favoring GP IIb/IIIa receptor antagonists over placebo (absolute rates of 5.5% vs 8.9% based on PCI trials of EPIC, IMPACT-II, EPILOG, CAPTURE,

TABLE 23-9 Pharmacologic Management of Percutaneous Coronary Intervention

Antiplatelet and antithrombotic adjuctive therapies for PCI–oral antiplatelet therapy	
Class I	
1. Patients already taking daily chronic aspirin therapy should take 75 to 325 mg of aspirin before the PCI procedure is performed. (Level of Evidence: A)	A daily dose of 75 mg of aspirin has been shown to result in improved cardiovascular outcomes similar to daily doses of 325 mg but with fewer bleeding complications.
2. Patients not already taking daily chronic aspirin therapy should be given 300–325 mg of aspirin at least 2 hours and preferably 24 hours before the PCI procedure is performed. (Level of Evidence: C)	Higher doses of aspirin are recommended for patients not already taking aspirin therapy immediately before PCI procedures.
3. After the PCI procedure, in patients with neither aspirin resistance, allergy, nor increased risk of bleeding, aspirin 325 mg daily should be given for at least 1 month after bare-metal stent implantation, 3 months after sirolimus-eluting stent implantation, and 6 months after paclitaxel-eluting stent implantation, after which daily chronic aspirin use should be continued indefinitely at a dose of 75 to 162 mg. (Level of Evidence: B)	The doses and duration of aspirin therapy recommended herein and derived from those used for US Food and Drug Administration approval of the specific stent types noted in the recommendation. Daily chronic aspirin therapy is based on recommendations in the ACC/AHA Guidelines for the Management of Patents with ST-Elevation Myocardial Infarction and evidence indicating that aspiring therapy in dosages as low as 75 mg per day yields outcomes similar to those achieved with 325 mg per day but with fewer side effects.
4. A loading dose of clopidogrel should be administered before PCI is performed. (Level of Evidence: A) An oral loading dose of 300 mg, administered at least 6 hours before the procedure, has the best established evidence of efficacy. (Level of Evidence: B)	Clopidogrel is an important adjunctive therapy for patients undergoing PCI with stent placement. The best evidence of efficacy exists for 300 mg given at lest 6 hours before PCI is performed.
5. In patients who have undergone PCI, clopidogrel 75 mg daily should be given for at least 1 month after bare-metal stent implantation (unless the patient is at increased risk for bleeding; then it should be given for a minimum of 2 weeks), 3 months after sirolimus stent implantation, and 6 months after paclitaxel stent implantation, and ideally up to 12 months for patients who are not at high risk of bleeding. (Level of Evidence: B)	Clopidogrel therapy in the dosage of 75 mg daily should be given after stent placement to all patients. The duration of therapy varies for each stent and is based on data from clinical trails used for U.S. Food and Drug Administration approval of that stent.
Class IIa	
1. If clopidogrel is given at the time of procedure, supplementation with GP IIb/IIIa receptor antagonists can be beneficial to facilitate earlier platelet inhibition than with clopidogrel alone. (Level of Evidence: B)	When clopidogrel is given at the time of a PCI procedure, supplementation with glycoprotein IIb/IIIa receptor antagonists can be beneficial, especially among high-risk patients.
2. For patients with an absolute contraindication to aspirin, it is reasonable to give a 300 mg loading dose of clopidogrel, administered at least 6 hours before PCI, and/or GP IIb/IIIa antagonists, administered at the time of PCI. (Level of Evidence: C)	A significant number of patients will have resistance to aspirin. The strongest evidence for clopidogrel benefit exists for doses of 300 mg given at least 6 hours before the procedure.
3. When a loading dose of clopidogrel is administered, a regimen of greater than 300 mg is reasonable to achieve higher levels of antiplatelet activity more rapidly, but the efficacy and safety compared with a 300-mg loading dose are less established. (Level of Evidence: C)	Many patients receive clopidogrel therapy at the time of PCI in dosages greater than 600 mg. Although more pronounced inhibition of platelet function has been demonstrated for doses of clopidogrel greater than 300 mg, the safety of these higher doses and their benefits on clinical outcome are not fully established.
4. It is reasonable that patients undergoing brachytherapy be given daily clopidogrel 75 mg indefinitely and daily aspirin 75 to 325 mg indefinitely unless there is significant risk for bleeding. (Level of Evidence: C)	Subacute or later thrombosis has been observed for patients undergoing brachytherapy, and for this reason long-term antiplatelet therapy is recommended.
Class IIb	
For patients in whom subacute thrombosis may be catastrophic or lethal (unprotected left main, bifurcating left main, or last patent coronary vessel), platelet aggregation studies may be considered and the dose of clopidogrel increased to 150 mg/day if less than 505 inhibition of platelet aggregation is demonstrated. (Level of Evidence: C)	Clopidogrel resistance is a significant problem, and owing to its contribution to catastrophic clinical outcomes, the Writing Committee recommends studies be performed with increases in clopidogrel dose being recommended for use in those with higher risk lesions.
Glycoprotein IIb/IIIa inhibitors	
Class I	
For patients with UA/NSTEMI undergoing PCI without clopidogrel administration, a C IIb/IIIa inhibitor (abciximab, eptifibatide, or tirofiban) should be administered. (Level of Evidence: A) It is acceptable to administer the GP IIb/IIIa inhibitor before performance of the diagnostic angiogram ("upstream treatment") or just before PCI ("in-lab treatment").	This recommendation and phrasing are compatible with the ACC/AHA 2002 Guideline Update for the Management of Patients with Unstable Angina and Non–ST-Segment Myocardial Infarction and current evidence from randomized clinical trials. The benefits of GP IIb/IIa inhibition are especially efficacious when clopidogrel is not given.

(continued)

TABLE 23-9 Pharmacologic Management of Percutaneous Coronary Intervention (continued)

Class IIa	
1. For patients with UA/NSTEMI undergoing PCI with clopidogrel administration, it is reasonable to administer a GP IIb/IIIa inhibitor (abciximab, eptifibatide, or tirofiban). (Level of Evidence: B) It is acceptable to administer the GP IIb/IIIa inhibitor before performance of the diagnostic angiogram ("upstream treatment") or just before PCI ("in-lab treatment").	
2. In patients with STEMI undergoing PCI, it is reasonable to administer abciximab as early as possible. (Level of Evidence: B)	Recommendation has been added for consistency with the ACC/AHA Guidelines for the Management of Patients With ST-Elevation Myocardial Infarction.
3. In patients undergoing elective PCI with stent placement, it is reasonable to administer a GP IIb/IIIa inhibitor (abciximab, epitifibatide, or tirofiban). (Level of Evidence: B)	Phrasing has been changed to reflect current terminology, especially in a high-risk patient.
Class IIb	
In patients with STEMI undergoing PCI, treatment with eptifibatide or tirofiban may be considered. (Level of Evidence: C)	Recommendation has been added for consistency with the ACC/AHA Guidelines for the Management of Patients with ST-Elevation Myocardial Infarction.
Antithrombotic therapy **Unfractionated heparin, low-molecular-weight heparin, and bivalirudin** **Class I**	
1. Unfractionated heparin should be administered to patients undergoing PCI. (Level of Evidence: C)	Phrasing has been changed to reflect current terminology.
2. For patients with heparin-induced thrombocytopenia, it is recommended that bivalirudin or argatroban be used to replace heparin. (Level of Evidence: B)	Bivalirudin and argatroban are established therapies in place of heparin among patients with heparin-induced thrombocytopenia.
Class IIa	
1. It is reasonable to use bivalirudin as an alternative to unfractionated heparin and glycoprotein IIb/IIIa antagonists in low-risk patients undergoing elective PCI. (Level of Evidence: B)	New recommendation is based on data from a clinical trial (REPLACE-2) indicating bivalirudin is an acceptable alternative to heparin and GP IIb/IIIa antagonists in low-risk patients undergoing PCI.
2. Low-molecular-weight heparin is a reasonable alternative to unfractionated heparin in patients with UA/NSTEMI undergoing PCI. (Level of Evidence: B)	Recommendation from the ACC/AHA 2002 Guideline Update for the Management of Patients with Unstable Angina and Non–ST-Segment Myocardial Infarction has been approved by this Writing Committee and included in these guidelines for consistency.
Class IIb	
Low-molecular-weight heparin may be considered as an alternative to unfractionated heparin in patients with STEMI undergoing PCI. (Level of Evidence: B)	Recommendation from the ACC/AHA Guidelines for the Management of Patients with ST-Elevation Myocardial Infarction has been approved by this Writing Committee and included in these guidelines for consistency.

GP, glycoprotein; NSTEMI, non–ST-segment elevation myocardial infarction; PCU, percutaneous coronary intervention; STEMI, ST-segment elevation myocardial infarction; UA, unstable angina.

RESTORE, and EPISTENT).[63] As discussed under unstable angina, high risk patients and those having a stent placed are most likely to benefit from GP IIb/IIIa receptor antagonist use. Patients presenting with elevated cardiac biomarkers are also more likely to receive benefit from GP IIb/IIIa receptor antagonists than patients with normal levels of biomarkers.[84] In the only comparative trial (TARGET), abciximab was superior to tirofiban.[85]

During PTCA, patients are usually heparinized to prevent immediate thrombus formation at the site of arterial injury and on coronary guidewires and catheters; anticoagulation is continued for up to 24 hours. The intensity of anticoagulation is monitored using the activated clotting time (ACT), and the targeted range for ACT is 250 to 300 seconds (HemoTec device) in the absence of GP IIb/IIIa receptor antagonist use.[63] When GP IIb/IIIa receptor antagonists are not used, UFH is given as an IV bolus of 70 to 100 international units/kg to achieve a target ACT of 200 seconds. The loading dose is lowered 50 to 70 international units/kg when GP IIb/IIIa receptor antagonists are given. Target ACT for eptifibatide and tirofiban is <300 seconds during angioplasty; postprocedural UFH infusions are not recommended during GP IIb/IIIa receptor antagonist therapy. Mechanisms that result in restenosis include acute lumen loss owing to "recoil," mural thrombosis formation, and smooth muscle cell proliferation with synthesis of extracellular matrix.[65] Approaches to prevent restenosis may be aimed at altering the underlying mechanisms. Recoil and loss of luminal diameter may be reduced by the use of stent placement; however, this beneficial effect is offset by an increased number of vascular complications. Cracking of the plaque leads to severe damage to the arterial wall, exposure of collagen, and endothelial dysfunction. These factors promote mural thrombi, and the propensity for thrombus formation is related, in part, to the composition of the plaque as well as the depth of injury. Combination therapy with ASA, heparin, and IIb/IIIa receptor antagonists is recommended to minimize acute occlusion and numerous clinical trials document the efficacy of this combined approach.[63,73,86] Bivalirudin is a specific and reversible direct thrombin inhibitor that is indicated for use as an anticoagulant for patients with unstable angina undergoing PTCA. Based on the REPLACE-2 and ACUITY studies, bivalirudin is comparable to heparin in preventing thrombosis and may be associated with less bleeding.[87,88] A more complete discussion of antithrombotic therapy can be found in Chap. 24.

When medical therapy, PTCA, and CABG have been compared, low-risk patients with single-vessel CAD and normal LV function had greater alleviation of symptoms with PTCA than those with medical treatment; mortality rates and rates of MI were unchanged. In high-risk patients (risk was defined by severity of ischemia, number of diseased vessels, and presence of LV dysfunction), improvement of survival was greater with CABG than with medical therapy. In moderate-risk patients with multivessel CAD (most had two-vessel disease and normal LV function), PTCA and CABG produced equivalent mortality rates and rates of MI.

The development of DES has changed the natural course of stent thrombosis when compared to bare metal stents (BMS) that have existed for a longer period of time. Currently there are three types of DES available: sirolimus (Cypher), paclitaxel (Taxus), and everolimus (Zortress). Soon after the introduction of BMS, it became apparent that early stent thrombosis (≤30 days) was an uncommon but serious complication of therapy.[65,76,79,89] Stent thrombosis is an infrequent but severe complication of both BMS and DES; while there is no apparent difference in overall stent thrombosis frequency at 4 years of follow-up, the time course appears to be different. There is a relative numeric excess of stent thrombosis late after DES implantation; however, no differences in death or death and infarction have been observed. Target lesion revascularization is needed less often with DES compared with BMS. Implantation of DES stents outside of approved indications and lack of proper positioning of the stent are related to the occurrence of late stent thrombosis. Longer-term follow-up with larger subsets of patients (i.e., lesion number, type and location, and patient comorbidities) is needed to fully understand this issue and the evolution of newer platforms for drug delivery will likely alter the natural history of DES stent thrombosis.[90] A very important consideration is the use of combination antiplatelet therapy (aspirin plus clopidogrel or prasugrel) for at least a year following implantation.[72,73,77,91] Patients who are unable to activate clopidogrel due to a reduced function allele for CYP2C19 may be treated with 150 mg/day rather than 75 mg/day or switched to prasugrel.[92] Drugs which inhibit CYP2C19 should probably be avoided although there is conflicting evidence in the literature.[93–95]

PHARMACOLOGIC THERAPY

Historically, about 30% of anginal syndrome symptoms have responded regardless of which therapy was instituted. These observations stem from two problems inherent in clinical trials undertaken to assess the efficacy of any therapy for angina: (1) adequate trial design incorporating appropriate controls and washout periods, and (2) assessment of treatment effects using objective measures of efficacy including improvement in exercise performance, resting and ambulatory ECG improvement in ischemic changes, or other objective tests to address other aspects of myocardial function or metabolism. The use of pain episode frequency and nitroglycerin consumption is subjective, and their use as sole measures of efficacy should be avoided. Objective assessment using ETT has shown that placebo does not provide improvement for patients with exertional angina, substantiating this as a valid means to assess efficacy.

β-Adrenergic Blocking Agents[96,97]

Decreased heart rate, decreased contractility, and a slight to moderate decrease in blood pressure with β-adrenergic receptor antagonism reduce MVO_2. The predominant receptor type in the heart is the β1-receptor, and competitive blockade minimizes the influence of endogenous catecholamines on the chronotropic and inotropic state of the myocardium. These beneficial effects may be countered to some degree with increased ventricular volume and ejection time seen with β-blockade; however, the overall effect of β-blockers for patients with effort-induced angina is a reduction in oxygen demand (Table 23–10). The β-blockers do not improve oxygen supply, and in certain instances, unopposed α-adrenergic stimulation following the use of β-blockers may lead to coronary vasoconstriction. For patients with chronic exertional stable angina, β-blockers improve symptoms about 80% of the time, and objective measures of efficacy demonstrate improved exercise duration and delay in the time at which ST-segment changes and initial or limiting symptoms occur. β-Blockers do not alter the rate-to-pressure product (double product) for maximal exercise, therefore substantiating reduced demand rather than improved supply as the major consequence of their actions. Reflex tachycardia from nitrate therapy can be blunted with β-blocker therapy, making this a common and useful combination. Although β-blockade may decrease exercise capacity in healthy individuals or for patients with hypertension, it may allow angina patients previously limited by symptoms to perform more exercise and ultimately improve overall cardiovascular performance through a training effect. Ideal candidates for β-blockers include patients in whom physical activity figures prominently in their anginal attacks, those who have coexistent hypertension, those with a history of supraventricular arrhythmias or post-MI angina, and those who have a component of anxiety associated with angina.[3] β-Blockers may also be safely used in angina and heart failure as described in Chap. 20. Pertinent pharmacokinetics for the β-blockers include half-life and route elimination, which are reviewed in Chap. 19. Drugs with longer half-lives need to be dosed less frequently than ones with shorter half-lives; however, disparity exists between half-life and duration of action for several β-blockers (e.g., metoprolol), and this may reflect attenuation of the central nervous system–mediated effects on the sympathetic system as well as the direct effects of this category on heart rate and contractility. Renal and hepatic dysfunction can affect the disposition of β-blockers, but these agents are dosed to effect, either hemodynamic or symptomatic, and route of elimination is not a major consideration in drug selection.

TABLE 23-10 Effect of Drug Therapy on Myocardial Oxygen Demand[a]

			LV Wall Tension

β-Blockers	⇓⇓	⇓	⇓	⇑
Nifedipine	⇓	0 or ⇓	0 or ⇓	0 or ⇓
Verapamil	⇓	⇓	⇓	0 or ⇓
Diltiazem	⇓⇓	0 or ⇓	⇓	0 or ⇓

LV, left ventricular.
[a]Calcium channel antagonists and nitrates also may increase myocardial oxygen supply through coronary vasodilation. Diastolic function also may be improved with verapamil, nifedipine, and perhaps diltiazem. These effects may vary from those indicated in the table depending on individual patient baseline hemodynamics.

Guidelines for the use of β-blockers in treating angina include the objective of lowering resting heart rate to 50 to 60 beats per minute and limiting maximal exercise heart rate to about 100 beats per minute or less. It has also been suggested that exercise heart rate should be no more than about 20 beats per minute or a 10% increment over resting heart rate with modest exercise. Because β-blockade is competitive and circulating catecholamine concentrations vary depending on the intensity of exercise and other factors and cholinergic tone may be important in controlling heart rate in some patients, these guidelines are general in nature. These effects are generally dose and plasma concentration related, and for propranolol, plasma concentrations of 30 ng/mL are needed for a 25% reduction of anginal frequency. Initial doses of β-blockers should be at the lower end of the usual dosing range and titrated to response as indicated above.

There is little evidence to suggest superiority of any β-blocker; however, the duration of β-blockade is dependent partially on the half-life of the agent used, and those with longer half-lives may

be dosed less frequently. Of note, propranolol may be dosed twice a day in most patients with angina, and the efficacy is similar to that seen with more frequent dosing. The ancillary property of membrane stabilizing activity is irrelevant in the treatment of angina, and intrinsic sympathomimetic activity appears to be detrimental in rest or severe angina because the reduction in heart rate would be minimized, therefore limiting a reduction in MVO_2. Cardioselective β-blockers may be used in some patients to minimize adverse effects such as bronchospasm in asthma, intermittent claudication, and sexual dysfunction. A common misunderstanding is that β-blockers are not well tolerated in peripheral arterial disease, but in fact, their use is associated with a reduction in death and improved quality of life.[98] It should be remembered that cardioselectivity is a relative property and that the use of larger doses (e.g., metoprolol 200 mg/day) is associated with the loss of selectivity and with adverse effects. Post-acute-MI patients with angina are particularly good candidates for β-blockade both because anginal symptoms may be treated as well as reducing the risk of post-MI reinfarction and because mortality has been demonstrated with timolol, propranolol, and metoprolol (see Chap. 24). Combined β- (nonselective) and α-blockade with labetalol may be useful in some patients with marginal LV reserve, and fewer deleterious effects on coronary blood flow are seen when compared with other β-blockers.

Extension of pharmacologic effect is the underlying reason for many of the adverse effects seen with β-blockade. Hypotension, decompensated heart failure, bradycardia and heart block, bronchospasm, and altered glucose metabolism are directly related to β-adrenoreceptor antagonism. Patients with preexisting LV systolic decompensated and heart failure and the use of other negative inotropic agents are most prone to developing overt heart failure, and in the absence of these, heart failure is uncommon (less than 5%). Other drugs that depress conduction are additive to β-blockade, and intrinsic conduction system disease predisposes the patient to conduction abnormalities. Altered glucose metabolism is most likely to be seen in insulin-dependent diabetics, and β-blockade obscures the symptoms of hypoglycemia except for sweating. β-Blockers may also aggravate the lipid abnormalities seen in patients with diabetes; however, these changes are dose related, are more common with normal baseline lipids than dyslipidemia, and may be of short-term significance only. One of the more common reasons for discontinuation of β-blocker therapy is related to central nervous system adverse effects of fatigue, malaise, and depression. Cognition changes seen with β-blockers are usually minimal and comparable to other categories of drugs based on studies done in hypertension.[99] Abrupt withdrawal of β-blocker therapy for patients with angina has been associated with increased severity and number of pain episodes and MI. The mechanism of this effect is unknown but may be related to increased receptor sensitivity or disease progression during therapy, which becomes apparent following discontinuation of β-blockade. In any event, tapering of β-blocker therapy over about 2 days should minimize the risk of withdrawal reactions for those patients in whom therapy is being discontinued.

β-adrenoreceptor blockade is effective in chronic exertional angina as monotherapy and in combination with nitrates and/or calcium channel antagonists. β-blockers should be the first-line drug in chronic angina requiring daily maintenance therapy because β-blockers are more effective in reducing episodes of silent ischemia, reducing early morning peak of ischemic activity, and improving mortality after Q-wave MI than nitrates or calcium channel blockers (Fig. 23–4).[3] If β-blockers are ineffective or not tolerated, then monotherapy with a calcium channel blocker may be instituted or, if monotherapy is ineffective for either alone, combination therapy may be instituted. Patients with severe angina, rest angina, or variant angina (i.e., a component of coronary artery spasm) may be better treated with calcium channel blockers or long-acting nitrates.

Nitrates[100]

Nitroglycerin has a well-documented role in the alleviation of acute anginal attacks when used as rapidly absorbed and readily available preparations by the oral and intravenous routes (see Table 23–10 and Table 23–11)). SL, buccal, or spray products are the products of choice for this indication. Prevention of symptoms may be accomplished by the prophylactic use of oral or transdermal products; however, recent concern has been expressed over the long-term efficacy of many of these preparations and the development of tolerance.[101–103]

Nitrates have multiple potential mechanisms of action, and for a given patient it is not always clear which of these is most important. In general, the major action appears to be indirectly mediated through a reduction of myocardial oxygen demand secondary to venodilation and arterial-to-arteriolar dilation, leading to a reduction in wall stress from reduced ventricular volume and pressure (see Table 23–10). Systemic venodilation also promotes increased flow to deep myocardial muscle by reducing the gradient between intraventricular pressure and coronary arteriolar (R2) pressure. Direct actions on coronary circulation include dilation of large and small intramural coronary arteries, collateral dilation, coronary artery stenosis dilation, abolition of normal tone in narrowed vessels, and relief of spasm; these actions occur even if the endothelium is denuded or dysfunctional. It is likely that depending on the underlying pathophysiology, different mechanisms become operative. For example, in the presence of a 60% to 70% stenosis, venodilation with MVO_2 reduction is most important; however, with higher grade lesions, direct effects on the coronary circulation and vessel tone are the predominant effects. Nitroglycerin and pentaerythritol tetranitrate (PETN) in low doses are bioactivated by mitochondrial aldehyde dehydrogenase (ALDH-2) to nitrite or dinitrated metabolites that require further activation by cytochrome oxidase or acidic disproportionation in the inner membrane space finally yielding nitric oxide. Nitric oxide activates soluble guanylate cyclase to increase intracellular concentrations of cyclic GMP resulting in vasorelaxation.[103] In contrast, isosorbide dinitrate (ISDN) and isosorbide mononitrate (ISMN) are bioactivated via CYP enzymes to nitric oxide. At higher concentrations, nitroglycerin and PETN may also be bioactivated to nitric oxide via CYP enzymes. Increased cyclic GMP induces a sequence of protein phosphorylation associated with reduced intracellular

TABLE 23-11 Nitrate Products

Product	Onset (minutes)	Duration	Initial Dose
Nitroglycerin			
IV	1–2	3–5 minutes	5 mcg/min
Sublingual/lingual	1–3	30–60 minutes	0.3 mg
Oral	40	3–6 hours	2.5–9 mg 3 times a day
Ointment	20–60	2–8 hours	0.5–1 in
Patch	40–60	>8 hours	1 patch
Erythritol tetranitrate	5–30	4–6 hours	5–10 mg 3 times a day
Pentaerythritol tetranitrate	30	4–8 hours	10–20 mg 3 times a day
Isosorbide dinitrate			
Sublingual/chewable	2–5	1–2 hours	2.5–5 mg 3 times a day
Oral	20–40	4–6 hours	5–20 mg 3 times a day
Isosorbide mononitrate	30–60	6–8 hours	20 mg daily, twice a day[a]

[a]Product dependent.

calcium release from the sarcoplasmic reticulum or reduced permeability to extracellular calcium and, consequently, smooth muscle relaxation. Oxidative stress within the mitochondria causes inactivation of ALDH-2 leading to impaired bioactivation of nitroglycerin during prolonged treatment.[104] Thomas et al.[101] performed a study in normal volunteers to evaluate the effect of ISMN 120 mg/day given for 7 days on endothelial function. They found that ISMN impaired endothelial function suggesting a role for oxygen free radicals and nitrate induced abnormalities in endothelial-dependent vasomotor responses that were reversed with a vitamin C infusion of 24 mg/min given for 15 minutes.[101] Furthermore, ISDN has been shown to impair flow mediated dilation and carotid intimal-media thickness after three months of treatment.[105] These deleterious changes in endothelial function, intima-media thickness and the occurrence of tolerance suggest that the role of nitrates in IHD may be changing.

Pharmacokinetic characteristics common to the organic nitrates used for angina include a large first-pass effect of hepatic metabolism, short to very short half-lives (except for ISMN), large volumes of distribution, high clearance rates, and large interindividual variations in plasma or blood concentrations. Pharmacodynamic-pharmacokinetic relationships for the entire class remain poorly defined, presumably due to methodological difficulty in characterizing the parent drug and metabolite concentrations at or within vascular smooth muscle and secondary to counterregulatory or adaptive mechanisms from the drug's effects as well as the occurrence of tolerance. Nitroglycerin is extracted by a variety of tissues and metabolized locally; differential extraction and metabolite generation occur depending on the tissue site. There are also numerous technical problems limiting the generation of reliable pharmacokinetic parameter estimates including the following: assay sensitivity; arteriovenous extraction gradients and therefore extrahepatic metabolism; in vitro degradation; drug adsorption to polyvinyl chloride tubing and syringes; potentially saturable metabolism; accumulation of metabolites (some of which are active) with multiple doses; postural and exercise-induced changes in pharmacokinetics; a variety of variables associated with transdermal delivery including the delivery system (matrix, membrane-limited, ointment); vehicle used; the surface area and thickness of application; the site application; and other skin variables (temperature, moisture content).

Nitroglycerin concentrations are affected by the route of administration, with the highest concentrations usually obtained with intravenous administration, the lowest seen with lower oral doses. Peak concentrations with SL nitroglycerin appear within 2 to 4 minutes, with the oral route producing peaks at about 15 to 30 minutes and by the transdermal route at 1 to 2 hours. The half-life of nitroglycerin is 1 to 5 minutes regardless of route; hence the potential advantage of sustained-release and transdermal products. Transdermal nitroglycerin does produce sufficient concentrations for acute hemodynamic effects to occur and these concentrations are maintained for long intervals; however, the hemodynamic and antianginal effects are minimal after 1 week or less with chronic, continuous (24 h/day) therapy.

ISDN is metabolized to isosorbide 2-mono- and 5-mononitrate ISMN. ISMN is well absorbed and has a half-life of about 5 hours and may be given once or twice daily depending on the product chosen. Multiple, larger doses of ISDN lead to disproportionate increases in the area under the plasma time profile, suggesting that metabolic pathways are being saturated or that metabolite accumulation may influence the disposition of ISDN. Little pharmacokinetic information is available for other nitrate compounds.

Nitrate therapy may be used to terminate an acute anginal attack, to prevent effort or stress-induced attacks, or for long-term prophylaxis, usually in combination with β-blockers or calcium channel blockers. SL nitroglycerin 0.3 to 0.4 mg will relieve pain in about 75% of patients within 3 minutes, with another 15% becoming pain free in 5 to 15 minutes. Pain persisting beyond about 20 to 30 minutes following the use of two or three nitroglycerin tablets is suggestive of ACS, and the patient should be instructed to seek emergency aid. Patients should be instructed to keep nitroglycerin in the original, tightly closed glass container and to avoid mixing with other medication, because mixing may reduce nitroglycerin adsorption and vaporization. Additional counseling should include the facts that nitroglycerin is not an analgesic but rather it partially corrects the underlying problem and that repeated use is not harmful or addicting. Patients should also be aware that enhanced venous pooling in the sitting or standing positions may improve the effect as well as the symptoms of postural hypotension and that inadequate saliva may slow or prevent tablet disintegration and dissolution. An acceptable albeit expensive alternative is lingual spray, which may be more convenient and has a shelf life of 3 years compared with 6 months or so for some forms of nitroglycerin tablets.

Chewable, oral, and transdermal products are acceptable for the long-term prophylaxis of angina; however, considerable controversy surrounds their use and it appears that the development of tolerance or adaptive mechanisms limits the efficacy of all chronic nitrate therapies regardless of route. Dosing of the longer acting preparations should be adjusted to provide a hemodynamic response, and as an example, this may require doses of oral ISDN ranging from 10 to 60 mg as often as every 3 to 4 hours owing to tolerance or first-pass metabolism, and similar large doses are required for other products. Nitroglycerin ointment has a duration of up to 6 hours, but it is difficult to apply in a cosmetically acceptable fashion over a consistent surface area, and its response varies depending on the epidermal thickness, vascularity, and amount of hair. Percutaneous adsorption of nitroglycerin ointment may occur unintentionally if someone other than the patient applies the ointment, and limiting exposure through the use of gloves or some other means is advisable.

Peripheral edema may also impair the response to nitroglycerin because venodilation cannot increase capacitance to a maximum and pooling may be reduced. Transdermal patch delivery systems were approved on the basis of sustained and equivalent plasma concentrations to other forms of therapy. Trials required by the Food and Drug Administration using transdermal patches as a continuous 24-hour delivery system revealed a lack of efficacy for improved exercise tolerance. Subsequently, large, randomized, double-blind, placebo-controlled trials of intermittent (10 to 12 hours on, 12 to 14 hours off) transdermal nitroglycerin therapy in chronic stable angina demonstrated modest but significant improvement in exercise time after 4 weeks for the highest doses at 8 to 12 hours after patch placement.[106] Subjective assessment methods for nitrate effects include reduction in the number of painful episodes and the amount of nitroglycerin consumed. Objective assessment includes the resolution of ECG changes at rest, during exercise, or with ambulatory ECG monitoring. Because nitrates work primarily through a reduction in MVO_2, the double product can be used to optimize the dose of SL and oral nitrate products. It is important to realize that reflex tachycardia may offset the beneficial reduction in systolic blood pressure and calculation of the observed changes is necessary. The double product is best assessed in the sitting position and at intervals of 5 to 10 minutes and 30 to 60 minutes following SL and oral therapy, respectively. Owing to the placebo effect, unpredictable and variable course of angina, numerous pharmacologic effects of nitroglycerin, diurnal variation in pain patterns, stringent investigative protocols, and interindividual sensitivity to nitroglycerin, assessment with transdermal and sustained-release products is difficult. ETT provides valuable

information concerning efficacy and mechanism of action for nitrates but its use is usually reserved for clinical investigation rather than routine patient care. Most ETT studies have shown nitrates to delay the onset of ischemia (ST-segment changes or initial chest discomfort) at submaximal exercise, but the threshold for maximal exercise is unaltered, suggesting a reduction in oxygen demand rather than an improved oxygen supply. More sophisticated studies of myocardial function such as wall motion abnormalities and myocardial metabolism could be used to document efficacy; however, these studies are generally only for investigative purposes.

Adverse effects of nitrates are related most commonly to an extension of their pharmacologic effects and include postural hypotension with associated central nervous system symptoms, headaches and flushing secondary to vasodilation, and occasional nausea from smooth muscle relaxation. If hypotension is excessive, coronary and cerebral filling may be compromised leading to MI and stroke. While reflex tachycardia is most common, bradycardia with nitroglycerin has been reported. Other noncardiovascular adverse effects include rash with all products but particularly with transdermal nitroglycerin, the production of methemoglobinemia with high doses given for extended periods, and measurable concentrations of ethanol (intoxication has been reported) and propylene glycol (found in the diluent) with intravenous nitroglycerin.

Tolerance with nitrate therapy was first described in 1867 with the initial experience using amyl nitrate for angina and later widely recognized in munitions workers who underwent withdrawal reactions during periods of absence from exposure. Tolerance to nitrates is associated with a reduction in tissue cyclic Guanyl Mono Phosphate (GMP), which results from decreased production (guanylate cyclase) and increased breakdown via cyclic GMP-phosphodiesterase and increased superoxide levels. One proposed mechanism for the lack of cyclic GMP is lack of conversion of organic nitrates to nitric oxide as described previously.[100]

Most of the published information from controlled trials examining nitrate tolerance have been done with either ISDN or transdermal nitroglycerin, and these studies demonstrate the development of tolerance within as little as 24 hours of therapy. While the onset of tolerance is rapid, the offset may be just as rapid, and one alternative dosing strategy to circumvent or minimize tolerance is to provide a daily nitrate-free interval of 6 to 8 hours. Studies with a variety of nitrate preparations and dosing schedules demonstrate that this approach is useful and the nitrate-free interval should be a minimum of 8 hours and perhaps 12 hours for even better effects.[100] Another concern for intermittent transdermal nitrate therapy is the occurrence of rebound ischemia during the nitrate-free interval. Freedman et al. found more silent ischemia during the patch-free interval during a randomized, double-blind, placebo-controlled trial than during the placebo patch phase, although others have not noted this effect.[107] ISDN, for example, should not be used more often than three times per day if tolerance is to be avoided. Interestingly, hemodynamic tolerance does not always coincide with antianginal efficacy, but this is not well studied.

Nitrates may be combined with other drugs for anginal therapy including β-adrenergic blocking agents and calcium channel antagonists. These combinations are usually instituted for chronic prophylactic therapy based on complimentary or offsetting mechanisms of action (Table 23–10). Combination therapy is generally used for patients with more frequent or symptoms not responding to β-blockers alone (nitrates plus β-blockers or calcium blockers), for patients intolerant of β-blockers or calcium channel blockers, and for patients having an element of vasospasm leading to decreased supply (nitrates plus calcium blockers).[108]

Calcium Channel Blockers

Modulation of calcium entry into vascular smooth muscle and myocardium as well as a variety of other tissues is the principle action of the calcium antagonists. The cellular mechanism of these drugs is not completely understood, and it differs among the available classes of the phenylalkylamines (verapamil-like), dihydropyridines (nifedipine-like), benzothiazepines (diltiazem-like), bepridil, and a recent class referred to as *T-channel blockers*. Receptor-operated channels stimulated by norepinephrine and other neurotransmitters, and potential-dependent channels activated by membrane depolarization, control the entry of calcium, and consequently the cytosolic concentration of calcium responsible for activation of actin–myosin complex leading to contraction of vascular smooth muscle and myocardium. In the myocardium, calcium entry triggers the release of intracellular stores of calcium to increase cytosolic calcium, whereas in smooth muscle calcium derived from the extracellular fluid may do this directly. Binding proteins within the cell, calmodulin and troponin, after binding with calcium, participate in phosphorylation reactions leading to contraction. Decreased calcium availability, through the actions of calcium antagonists, inhibits these reactions. Direct actions of the calcium antagonists include vasodilation of systemic arterioles and coronary arteries, leading to a reduction of arterial pressure and coronary vascular resistance as well as depression of the myocardial contractility and conduction velocity of the sinoatrial and atrioventricular nodes (see Chap. 25). Reflex β-adrenergic stimulation overcomes much of the negative inotropic effect, and depression of contractility becomes clinically apparent only in the presence of LV dysfunction and when other negative inotropic drugs are used concurrently. Verapamil and diltiazem cause less peripheral vasodilation than nifedipine, and, consequently, the risk of myocardial depression is greater with these two agents. Conduction through the AV node is predictably depressed with verapamil and diltiazem, and they must be used with caution for patients with preexisting conduction abnormalities or in the presence of other drugs with negative chronotropic properties. MVO_2 is reduced with all of the calcium channel antagonists because of reduced wall tension secondary to reduced arterial pressure and, to a minor extent, depressed contractility (Table 23–10). Heart rate changes are dependent on the drug used and the state of the conduction system. Nifedipine generally increases heart rate or causes no change whereas either no change or decreased heart rate is seen with verapamil and diltiazem because of the interaction of these direct and indirect effects. In contrast to the β-blockers, calcium channel antagonists have the potential to improve coronary blood flow through areas of fixed coronary obstruction and by inhibiting coronary artery vasomotion and vasospasm. Beneficial redistribution of blood flow from well-perfused myocardium to ischemic areas and from epicardium to endocardium may also contribute to improvement in ischemic symptoms. Overall, the benefit provided by calcium channel antagonists is related to reduced MVO_2 rather than improved oxygen supply based on lack of alteration in the rate pressure product at maximal exercise in most studies performed to date. However, as CAD progresses and vasospasm becomes superimposed on critical stenotic lesions, improved oxygen supply through coronary vasodilation may become more important.

Absorption of the calcium channel antagonists is characterized by excellent absorption and large, variable first-pass metabolism resulting in oral bioavailability ranging from about 20% to 50% or greater for diltiazem, nicardipine, nifedipine, verapamil, felodipine, and isradipine. Amlodipine has a range of bioavailability

of ~60% to 80%. Saturation of this effect may occur with verapamil and diltiazem, resulting in greater amounts of drug being absorbed with chronic dosing. Nifedipine may have slow or fast absorption patterns, and the ingestion of food delays and impairs its absorption as well as potential enhanced absorption in elderly patients. This variability in absorption produces fluctuation in the hemodynamic response with nifedipine. SL nifedipine is frequently used to provide a more rapid response; however, the rationale for this application is suspect because little nifedipine is absorbed from the buccal mucosa and the swallowed drug is responsible for the observed plasma concentrations. Absorption of verapamil in sustained-release products may be influenced by food, and when used in the fasted state, dose dumping may occur, resulting in high peak concentrations with some products. The approved sustained-release products for nifedipine, verapamil, and diltiazem are approved primarily for the treatment of hypertension (see Chapter 19). The presence of severe liver disease (e.g., alcoholic liver disease with cirrhosis) has been shown to reduce the first-pass metabolism of verapamil, and this shunting of drug around the liver gives rise to higher plasma concentrations and lower dose requirements in these patients. Interestingly, this effect appears to be stereoselective for the more active isomer of verapamil. Verapamil may also reduce liver blood flow; however, evidence for this reduction is based primarily on animal experiments. Few data are available regarding the influence of liver disease on the kinetics of calcium blockers; however, these drugs undergo extensive hepatic metabolism with little unchanged drug being renally excreted, and liver disease can be expected to alter the pharmacokinetics. Nifedipine has no active metabolites whereas norverapamil possesses 20% or less activity of the parent compound. Desacetyldiltiazem has not been studied in man, but canine studies suggest its potency ranges from 100% to 40% of the parent compound for various cardiovascular effects; the clinical importance of these observations remains to be determined. With chronic dosing of verapamil and diltiazem, apparent saturation of metabolism occurs, producing higher plasma concentrations of each drug than those seen with single-dose administration. Consequently, the elimination half-life for verapamil is prolonged, and less frequent dosing intervals may be used in some patients. The elimination half-life for diltiazem is also somewhat prolonged and the half-life of desacetyldiltiazem is longer than that of the parent drug, but it is not clear if less frequent dosing may be used. Bepridil also undergoes hepatic elimination and an active metabolite, 4-hydroxyphenyl bepridil, is produced; the parent compound has a long half-life of 30 to 40 hours. Nifedipine does not accumulate with chronic dosing; however, it is eliminated via oxidative pathways that may be polymorphic, and slow and fast metabolizers have been described for nifedipine. Most of the calcium channel blockers are eliminated via cytochrome (CYP) 3A4 and other CYP isoenzymes and many inhibit CYP 3A4 activity as well. Renal insufficiency has little or no effect on the pharmacokinetics of these three drugs. Although disease alterations in kinetics have been described, the most important quantitative alteration is the influence of liver disease on bioavailability and elimination that reduce the clearance of verapamil and diltiazem, and dosing in this population should be done with caution. Altered protein binding due to renal disease, decreased protein concentration, or increased α1-acid glycoprotein has been noted, but the clinical import of these changes is unknown.

Good candidates for calcium channel blockers in angina include patients with contraindications or intolerance of β-blockers, coexisting conduction system disease (except for verapamil and diltiazem), patients with Prinzmetal angina (vasospastic or variable threshold angina), the presence of peripheral vascular disease, severe ventricular dysfunction (amlodipine is probably calcium channel blocker of choice and others need to be used with caution if the ejection fraction is <40%), and concurrent hypertension.

Ranolazine

Ranolazine is a new drug for angina that has a unique mechanism of action unlike any other drugs used to alter the relationship between oxygen supply and demand. Ranolazine reduces calcium overload in the ischemic myocyte through inhibition of the late sodium current (I_{Na}). Myocardial ischemia produces a cascade of complex ionic exchanges that can result in intracellular acidosis, excess cytosolic Ca^{2+}, myocardial cellular dysfunction, and, if sustained, cell injury and death. Activation of the adenosine triphosphate–dependent K^+ current during ischemia results in a strong efflux of K^+ ions from myocytes. Sodium channels are activated on depolarization, leading to a rapid influx of sodium into the cells. The inactivation of I_{Na} has a fast component lasting a few milliseconds and a slowly inactivating component that can last hundreds of milliseconds.[109] Ranolazine is a relatively selective inhibitor for late I_{Na}. In isolated ventricular myocytes in which the late I_{Na} was pathologically augmented, ranolazine prevented or reversed the induced mechanical dysfunction, as well as ameliorated abnormalities of ventricular repolarization. Ranolazine does not affect heart rate, inotropic state, or hemodynamic state or increase coronary blood flow.

Ranolazine is extensively metabolized via CYP 450 3A and potent inhibitors of 3A increase the plasma concentration by a factor of about three. Ketoconazole, diltiazem, and verapamil should not be coadministered with ranolazine. Absorption from the gut is quite variable and the apparent half-life is 7 hours. Steady state is reached after 3 days of twice daily dosing. Ranolazine is indicated for the treatment of chronic angina, and because it prolongs the QT interval, it should be reserved for patients who have not achieved an adequate response with other antianginal agents. Contraindications include preexisting QT interval prolongation, hepatic impairment, concurrent QT interval prolonging drugs and moderately potent to potent concurrent 3A inhibitors. QT prolongation occurs in a dose-dependent fashion with ranolazine with an average increase of 6 milliseconds, but 5% of the population has QTc prolongation of 15 milliseconds. Baseline and follow-up ECGs should be obtained to evaluate effects of the QT interval. In controlled trials, the most common adverse reactions are dizziness, headache, constipation, and nausea. Ranolazine should be started at 500 mg twice daily and increased to 1000 mg twice daily as needed based on symptoms.[110]

Based on randomized, placebo-controlled trials, the improvement in exercise time is a modest increase of 15 to about 45 seconds compared with placebo.[111–113] In a large ACS trial, ranolazine reduced recurrent ischemia but did not improve the primary efficacy end point of the composite of cardiovascular death, MI, or recurrent ischemia.[114] Ranolazine may have antiarrhythmic effects as assessed by continuous ECG monitoring of patients in the first week after admission for ACS.[115]

Coronary Artery Spasm and Variant Angina Pectoris (Prinzmetal Angina)

Prinzmetal, in his original description of variant angina pectoris, noted the waxing and waning course of this syndrome associated with ST-segment elevation and most commonly resolves without progression to MI. Patients who develop variant angina are usually younger, have fewer coronary risk factors, but more commonly smoke than patients with chronic stable angina. Hyperventilation, exercise,

exposure to cold may precipitate variant angina attacks or there may be no apparent precipitating cause. The onset of chest discomfort is usually in the early morning hours. The exact cause of variant angina is not well understood, but may be an imbalance between endothelium-produced vasodilator factors (prostacyclin, nitric oxide) and vasoconstrictor factors (e.g., endothelin, angiotensin II) as well as an imbalance of autonomic control characterized by parasympathetic dominance, or inflammation may also play a role.[116,117] More recently there have been a number potential common adrenoreceptor polymorphisms that may predispose patients to developing vasospasm.[118–121] Another possible explanation is a recently discovered genetic mutation. The eNOS T-786C mutation appears to be a reversible etiology of Prinzmetal variant angina in white Americans whose angina might be ameliorated by L-arginine.[119]

The diagnosis of variant angina is based on ST-segment elevation during transient chest discomfort (usually at rest) that resolves when the chest discomfort diminishes for patients who have normal or nonobstructive coronary lesions. In the absence of ST-segment elevation, a provocative test using ergonovine, acetylcholine, or methacholine may be used to precipitate coronary artery spasm, ST-segment elevation, and typical symptoms. Nitrates and calcium antagonists should be withdrawn prior to provocative testing. Provocative testing should not be used for patients with high-grade lesions. Hyperventilation may also be used to provoke spasm, and patients who have positive a hyperventilation test are more likely to have higher frequency of attacks, multivessel disease, and a high degree of AV block or ventricular tachycardia.

Optimization of therapy includes dose titration using sufficiently high doses to obtain clinical efficacy without unacceptable adverse effects in individual patients. All patients should be treated for acute attacks and maintained on prophylactic treatment for 6 to 12 months following the initial episode. The occurrence of serious arrhythmias during attacks is associated with a greater risk of sudden death, and these patients should be treated more aggressively and for prolonged periods. For patients without arrhythmias who become asymptomatic and remain so for several months after treatment has been instituted, withdrawal of therapy may be safe after first ascertaining that disease activity is quiescent. Aggravating factors such as alcohol or cocaine use or cigarette smoking should be eliminated when instituting treatment.

Nitrates have been the mainstay of therapy for the acute attacks of variant angina and coronary artery spasm for many years. Most patients respond rapidly to SL nitroglycerin or ISDN; however, intravenous and intracoronary nitroglycerin may be very useful for patients not responding to SL preparations. In particular, vasospasm provoked by ergonovine may require intracoronary nitroglycerin. Although studies with nitrates generally show them to be efficacious, high does are often required, and it is unclear if they reduce mortality. Because calcium antagonists may be more effective, have few serious adverse effects in effective doses, and can be given less frequently than nitrates, some consider them the agents of choice for variant angina.

Nifedipine, verapamil, and diltiazem are all equally effective as single agents for the initial management of variant angina and coronary artery spasm. Dose titration is important to maximize the response with calcium antagonists. Comparative trials, which are few number and do not reveal significant differences among these three drugs for variant angina. Patients unresponsive to calcium antagonists alone may have nitrates added. Combination therapy with nifedipine–diltiazem or nifedipine–verapamil has been reported useful for patients unresponsive to single-drug regimens. This is probably rational because, at the cellular level, the drugs have different receptors, but the combination of verapamil–diltiazem should be used cautiously owing to their potential additive effects on contractility and conduction.

β-adrenergic blockade has little or no role in the management of variant angina according to most authorities.[120] Although not all studies report increased painful episodes of variant angina with the addition of β-blockers, they may induce coronary vasoconstriction and prolong ischemia, as documented by continuous ECG monitoring. Other approaches to therapy attempting to modify sympathetic/parasympathetic tone include α-antagonists, anticholinergics, plexectomy, surgical interruption of the sympathetic innervation of the heart, thromboxane receptor antagonism, prostacyclin, lipoxygenase inhibition, and ticlopidine but these drugs or procedures do not occupy a major place in therapy at the present time. One interesting case report found that the likely cause of MI was coronary artery spasm in a woman with migraine headaches because of the possible increased serotonergic activity secondary to concomitant use of zolmitriptan and citalopram.[121]

Silent Ischemia[16]

The objective in the treatment of silent myocardial ischemia is to reduce the total number of ischemic episodes, both symptomatic and asymptomatic, regardless of the direction of ST-segment shift. The incidence of silent ischemia in the general, asymptomatic population is not known. Significant day-to-day variability in the number of episodes, the duration of ischemia, and the amount of ST-segment deviation complicates both the understanding of this process and the utility of various therapeutic interventions. Silent ischemia for patients with known CAD is common (~80% of all ischemic episodes) and associated with the extent of disease as well as a high risk for MI and sudden death when compared with symptomatic episodes of ischemia. Although the underlying mechanisms for silent ischemia are continuing to be defined, increased physical activity, activation of the sympathetic nervous system, increased cortisol secretion, increased coronary artery tone, and enhanced platelet aggregation due to endothelia dysfunction leading to intermittent coronary obstruction may be additive in lowering the threshold for ischemia. Platelet aggregability is increased in the morning hours (7 AM to 11 AM), corresponding to circadian rhythms noted for the peak frequency of ischemia, AMI, and sudden death. Silent ischemia is associated with ST-segment elevation or depression and frequently occurs without antecedent changes in heart rate or blood pressure, suggesting that this form of ischemia is a result of primary reduction in oxygen supply. Silent ischemia is classified into Class I, patients who do not experience angina at any time, and Class II, patients who have both asymptomatic and symptomatic ischemia. Patients with silent ischemia have a defective warning system for angina pain that may encourage excessive myocardial demand. Regardless of the exact mechanism, there is increasing concern that painless ischemia carries considerable risk for myocardial perfusion defects, detrimental hemodynamic changes, arrhythmogenesis, and sudden death.[122] Silent ischemia is associated with reduced survival and increased need for PTCA and CABG as well as increased risk of AMI.[123,124] Because it is apparently very common in some settings, major emphasis should be placed on its management. A consensus has not been reached for the most appropriate method of detecting and quantifying the magnitude of silent ischemia; however, ambulatory electrocardiogram monitoring is felt by many to be the most useful tool at the present time.

The initial step in management is to modify the major risk factors for IHD, hypertension, hypercholesterolemia, and smoking, and data from the Multiple Risk Factor Intervention Trial (MRFIT) show these interventions to be useful for patients with silent ischemia. In a subset of the study population who had abnormal baseline exercise ECG responses, the special intervention group

had a 57% reduction in CHD death (22.2/1000 vs 51.8/1000) and a reduction in sudden death resulting from cessation of smoking and lowering of blood pressure and cholesterol when compared with the usual-care group.

Asymptomatic Cardiac Ischemia Pilot (ACIP), a randomized trial of medical therapy versus revascularization (PTCA or CABG), at the 2-year follow-up demonstrates that total mortality was 6.6% in the angina-guided strategy (i.e., therapy based on symptoms), 4.4% in the ischemia-guided strategy (based on ECG changes), and 1.1% in the revascularization strategy ($P<0.02$). The rate of death or MI was 12.1% in the angina-guided strategy, 8.8% in the ischemia-guided strategy, and 4.7% in the revascularization strategy ($P<0.04$).[124] The rate of death, MI, or recurrent cardiac hospitalization was 41.8% in the angina-guided strategy, 38.5% in the ischemia-guided strategy, and 23.1% in the revascularization strategy ($P<0.001$). Post-MI patients and those with a high level of sympathetic nervous system activity are perhaps the best candidates for β-blocker therapy.

Calcium channel antagonists alone and in combination have been shown to be effective in reducing symptomatic and asymptomatic ischemia; however, they do not interrupt the diurnal surge in ischemia observed on ambulatory monitoring and, in general, they are somewhat less effective than β-blockers for silent ischemia.[125,126] Nifedipine in particular seems to provide less protection and provides wide fluctuations in response with approximate reductions in the number of episodes ranging from 0% to 93% and in duration from 23% to 65% unless combined with β-blockers. Fewer studies are available with other calcium blockers and comparative trials are uncommon. Earlier studies have shown that combination therapy with calcium and β-blockers provides a better response than calcium blockers and nitrates or monotherapy.[124,127]

A randomized, unblinded, controlled trial Swiss Interventional Study on Silent Ischemia Type II (SWISSI II) of PCI for patients with silent ischemia after AMI found that PCI compared with antiischemic drug therapy reduced the long-term risk of major cardiac events with better preservation of ventricular function than with medical therapy.[128,129]

PHARMACOECONOMIC CONSIDERATIONS

Pharmacoeconomic studies have been performed primarily for patients with ACSs and only with low molecular weight heparins, glycoprotein IIb/IIIa receptor antagonists and statins.[130] Most of the studies on LMWHs have been cost-minimization analyses and have focused on enoxaparin sodium, because this is the only LMWH proven to be superior to UFH. Several analyses show that, compared with UFH plus aspirin, enoxaparin sodium provides cost savings both during hospitalization (30 days) and 1-year follow-up. These cost savings are mainly attributable to fewer cardiac interventions, shorter hospital stays, and lower administrative costs. Indeed, the clinical and economic advantages of enoxaparin sodium have led to its recommendation in recent guidelines as the antithrombotic agent of choice for CAD. Most of the economic analyses of GP IIb/IIIa inhibitors have been cost-effectiveness analyses.[131] Such analyses indicate that the high acquisition costs of these drugs may be at least partially offset by reductions in other costs if a noninvasive approach to risk stratification is used. Furthermore, use of GP IIb/IIIa inhibitors appears to give favorable cost-effectiveness ratios compared with other accepted therapies, such as fibrin-specific thrombolytic therapy, in the cardiovascular field, particularly in high-risk patients and those undergoing percutaneous coronary intervention. However, more comprehensive economic data on the GP IIb/IIIa inhibitors are needed. Bivalirudin combined with provisional glycoprotein IIb/IIIa inhibitors appears to be an acceptable alternative to the standard of care, is superior to UFH alone in PCI, and is considered to be cost effective.[132]

Atorvastatin when used in ACS has been shown to reduce events and this offsets the upfront acquisition costs.[133] The total expected cost was £784.05 (British) per patient in the placebo cohort and £851.59 per patient in the atorvastatin cohort, resulting in an incremental cost of £67.54 per patient in the atorvastatin group. The cost per event avoided was £1762.04. A third of the cost of atorvastatin treatment was offset within 16 weeks by the cost savings resulting from the reduction in the number of events in the atorvastatin cohort compared with the placebo cohort. Other analyses of statins have found this class to be cost-effective especially for patients at higher risk.[133]

Aspirin and clopidogrel have been evaluated for secondary prevention of CHD, and while aspirin is very cost effective, clopidogrel is only cost effective or patients who cannot take aspirin.[134]

CLINICAL CONTROVERSIES

Once patients with angina develop symptoms sufficient for pharmacologic therapy on a daily basis, the initial prophylactic therapy recommended is a β-blocker. There is a paucity of comparative, long-term clinical trials of β-blockade versus calcium channel blockers to determine which is superior for survival benefit. β-blockers are recommended first-line therapy because of their efficacy in post-MI patients and favorable adverse effect profile.

Recent developments in the understanding of bioactivation of organic nitrates have given rise to concern over endothelial dysfunction induced by nitrates when administered long term. Not all nitrate products are activated via the same mechanisms, and this may impact how effective individual drugs are in long-term treatment.

In stable CAD, medical management has been reported for outcomes similar to revascularization, and these findings may have a significant impact on how healthcare resources are utilized in the future.

EVALUATION OF THERAPEUTIC OUTCOMES

Improved symptoms of angina, improved cardiac performance and improvement in risk factors may all be used to assess the outcome of treatment of IHD and angina. Symptomatic improvement in exercise capacity (longer duration) or fewer symptoms at the same level of exercise is subjective evidence that therapy is working. Once patients have been optimized on medical therapy, symptoms should improve over 2 to 4 weeks and remain stable until their disease progresses. There are several instruments (e.g., Seattle angina questionnaire, specific activity scale [Table 23–1], Canadian classification system [Table 23–2]) that could be used improve the reproducibility of symptom assessment.[2] If the patient is doing well, then no other assessment may be necessary. Objective assessment is obtained through increase exercise duration on ETT and the absence of ischemic changes on ECG or deleterious hemodynamic changes. Echocardiography and cardiac imaging may also be used, however, due to their expense, they are only used if a patient is not doing well to determine if revascularization or other measures should be undertaken. Coronary angiography may be used to assess the extent of stenosis or re-stenosis after angioplasty or CABG. 11 The performance measurement set recommended by the ACC/AHA is provided in Table 23–12.

TABLE 23-12 American College of Cardiology, American Heart Association, and Physician Consortium for Performance Improvement Chronic Stable Coronary Artery Disease Core Physician Performance Measurement Set[a]

	Clinical Recommendations
Blood pressure measurement	A blood pressure ready is recommended at every visit. Recommended blood pressure management targets are ≤130 mm Hg systolic (Class I Recommendation, Level A Evidence) and ≤85 mm Hg diastolic for patients with CAD coexisting condition (e.g., diabetes, heart failure, or renal failure) and <140/90 mm Hg for patients with CAD and no coexisting condition.
Lipid profile	A lipid profile is recommended and should include total cholesterol, high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C), and triglycerides. (*Class I Recommendation, Level C Evidence*)
Symptom and activity assessment	Regular assessment of patients' anginal symptoms and levels of activity is recommended. (Serves as a basis for treatment modification.)
Smoking cessation	Smoking status should be determined and smoking cessation counseling and interventions are recommended. (*Class I Recommendation, Level B Evidence*)
Antiplatelet therapy[d] *Denominator exclusion* Documentation of medical reason(s)[b] for not prescribing antiplatelet therapy; documentation of patient reason(s)[c] for not prescribing antiplatelet therapy	Routine use of aspirin is recommended in the absence of contraindications. If contraindications exist, other antiplatelet therapies may be substituted. (*Class I Recommendation, Level A Evidence*)
Drug therapy for lowering LCL-cholesterol *Denominator exclusion* Documentation that a statin was not indicated;[e] documentation of medical reason(s)[b] for not prescribing a statin; documentation of patient reason(s)[c] for not prescribing statin	The LCL-C treatment goal is <100 mg/dL. Persons with established coronary heart disease (CHD) who have a baseline LCL-C ≥130 mg/dL should be started on a cholesterol-lowering drug simultaneously with therapeutic lifestyle changes and control of nonlipid risk factors. (*Class I Recommendation, Level A Evidence*)
β-blocker therapy–prior myocardial infarction (MI) *Denominator inclusion* Prior MI *Denominator exclusion* Documentation that a β-blocker was not indicated; documentation of medical reason(s)[b] for not prescribing a β-blocker; documentation of patient reason(s)[c] for not prescribing a β-blocker	β-Blocker therapy is recommended for all patients with prior MI in the absence of contraindications. (*Class I Recommendation, Level A Evidence*)
ACE inhibitor therapy *Denominator inclusion* Patient with CAD who also has diabetes and/or left ventricular systolic dysfunction (LVSD) (left ventricular ejection fraction [LVEF] <40% or moderately or severely depressed left ventricular systolic function) *Denominator exclusion* Documentation that ACE inhibitor was not indicated (e.g., patients on angiotensin receptor blockers [ARB]); documentation of medical reason(s)[b] for not prescribing ACE inhibitor; documentation of patient reason(s)[c] for not prescribing ACE inhibitor	ACE inhibitor use is recommended in all patients with CAD who also have diabetes and/or LVSD (*Class I Recommendation, Level A Evidence*) ACE inhibitor use is also recommended in patients with CAD or other vascular disease (*Class IIa Recommendation, Level B Evidence*)
Screening for diabetes[f,g] *Denominator exclusion* Patients with documented diabetes	Screening for diabetes is recommended in patients who are considered high risk (e.g., CAD) (*Class I Recommendation, Level A Evidence*)

ACE, angiotensin-converting enzyme; CAD, coronary artery disease; MI, myocardial infarction.

[a]Refers to all patients diagnosed with CAD

[b]Medical reasons for not prescribing *antiplatelet therapy* (aspirin, clopidogrel, or combination of aspirin and dipyridamole): active bleeding in the previous 6 months with required hospitalization and/or transfusion(s), patient on other antiplately therapy, etc. Medical reasons for not prescribing a *statin*: clinical judgement, documented LCL-C <130 mg/dL, etc. Medical reasons for not prescribing a *β-blocker*: bradycardia (defined as heart rate <50 beats/min without β-blocker therapy), history of class IV (congestive) heart failure, history of secondor third-degree atrioventricular block without permanent pacemaker, etc. Medical reasons for not prescribing *ACE inhibitor* (ACEI): allergy, angioedema caused by ACEI, anuric rental failure caused by ACEI, pregnancy, moderate or severe aortic stenosis, etc.

[c]Patient reasons for not prescribing antiplatelet therapy, statin, β-blocker, or ACEI: economic, social, and/or religious, etc.

[d]Antiplatelet therapy may include aspirin, clopidogrel, or combination of aspirin and dipyridamole.

[e]Not indicated for a stat refers to LCL-C <100 mg/dL.

[f]Test measure.

[g]Screening for diabetes is usually done by fasting blood glucose or 2-hour glucose tolerance testing. Clinical recommendations indicate screening should be considered at 3-year intervals.

CHAPTER 24

Acute Coronary Syndromes

SARAH A. SPINLER AND SIMON DE DENUS

KEY CONCEPTS

1. The cause of an acute coronary syndrome (ACS) is the erosion or rupture of an atherosclerotic plaque with subsequent platelet adherence, activation, aggregation, and activation of the clotting cascade. Ultimately, a clot forms and is composed of fibrin and platelets.
2. The American Heart Association (AHA) and the American College of Cardiology (ACC) recommend strategies or guidelines for ACS patient care for ST-segment elevation (STE) myocardial infarction (MI) and unstable angina, non-ST-segment elevation (NSTE) MI, also termed NSTE ACS.
3. Patients with ischemic chest discomfort and suspected ACS are risk stratified based on a 12-lead electrocardiogram (ECG), past medical history, signs and symptoms, and results of creatine kinase myocardial band (CK-MB) and troponin biochemical marker tests.
4. The diagnosis of MI is confirmed based on the results of the CK-MB and troponin tests.
5. Early reperfusion therapy with either primary percutaneous coronary intervention (PCI) or administration of a fibrinolytic agent is the recommended therapy for patients presenting with STE MI.
6. High-risk patients with NSTE ACS should undergo early coronary angiography and revascularization with either PCI or coronary artery bypass graft (CABG) surgery.
7. In addition to reperfusion therapy, additional pharmacotherapy that all patients with STE MI and without contraindications should receive within the first day of hospitalization and preferably in the emergency department are intranasal oxygen (if oxygen saturation is low), aspirin, a thienopyridine (agent and timing dependent on reperfusion strategy), sublingual (SL) nitroglycerin (NTG), and anticoagulation with either bivalirudin, unfractionated heparin (UFH), or enoxaparin (agent dependent on reperfusion strategy). A glycoprotein IIb/IIIa inhibitor should be administered with UFH for patients undergoing primary PCI. Intravenous (IV) β-blockers and NTG should be given to select patients.
8. In the absence of contraindications, all patients with NSTE ACS should be treated in the emergency department with intranasal oxygen (if oxygen saturation is low), aspirin, SL NTG, and an anticoagulant, either UFH, enoxaparin, fondaparinux, or bivalirudin. High-risk patients should proceed to early coronary angiography and may additionally receive a glycoprotein IIb/IIIa inhibitor. Clopidogrel or prasugrel [agent and timing dependent on selection of an interventional (PCI) or medical management strategy] should be administered to all patients. Intravenous β-blockers and nitroglycerin should be given to select patients.
9. Following MI, all patients, in the absence of contraindications, should receive indefinite therapy with aspirin, a β-blocker (started within 24 hours of hospital arrival), and an angiotensin-converting enzyme (ACE) inhibitor for secondary prevention of death, stroke, and recurrent infarction. Most patients will receive a statin to reduce low-density lipoprotein cholesterol to less than 100 mg/dL and ideally less than 70 mg/dL. Clopidogrel or prasugrel should be continued for at least 12 months for patients undergoing PCI, and clopidogrel should be continued for at least 14 days in patients with STE MI who either did not receive reperfusion therapy or received fibrinolytic therapy without PCI and who are at low risk of bleeding. Anticoagulation with warfarin should be considered for patients at high risk of death, reinfarction, or stroke.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Since the early 1900s, cardiovascular disease (CVD) has been the leading cause of death. Acute coronary syndromes (ACSs), including unstable angina (UA) and myocardial infarction (MI), are forms of coronary heart disease (CHD) that constitute the most common cause of CVD death.[1] 1 The cause of an ACS is the erosion or rupture of an atherosclerotic plaque with subsequent platelet adherence, activation, aggregation, and activation of the clotting cascade. Ultimately, a clot forms in the culprit coronary artery and is composed of fibrin and platelets. Correspondingly, pharmacotherapy of ACS has advanced to include combinations of fibrinolytics, antiplatelets, and anticoagulants with more traditional therapies such as nitrates and β-adrenergic blockers. Pharmacotherapy is integrated with reperfusion therapy and revascularization of the culprit coronary artery through interventional means such as percutaneous coronary intervention (PCI) and coronary artery bypass graft (CABG) surgery. 2 The American Heart Association (AHA) and the American College of Cardiology (ACC) recommend strategies or guidelines for ACS patient care for ST-segment elevation (STE) myocardial infarction (MI) and non-ST-segment elevation (NSTE) ACS. These joint practice guidelines are based on a review of available clinical evidence, have graded recommendations based on the weight and quality of evidence, and

are updated periodically. The guidelines form the cornerstone for quality patient care of the ACS patient.[2–6]

EPIDEMIOLOGY

Each year more than 1.2 million Americans will experience an ACS, and 220,000 will die of an MI.[1] In the United States, more than 17.6 million, or 7.9% of living persons age 20 years and older, have CHD, and 3.6% have survived an MI.[1] Chest discomfort is the most frequent specific reason for patient presentation to emergency departments with up to 6.3 million emergency department visits, or approximately 5.4% of all emergency department visits, linked to chest discomfort and possible ACS.[7] CHD is the leading cause of premature, chronic disability in the United States. The cost of CHD is high, with direct and indirect costs estimated at $177.1 billion for 2010.[1] The median length of hospital stay for MI in 2001 was 4 days but had decreased to a median of 3 days in 2006.[1]

Much of the epidemiologic data regarding ACS treatment and survival come from the ACC's National Cardiovascular Data Registry (NCDR) Acute Coronary Treatment and Interventions Network (ACTION)—Get with the Guidelines (GWTG), the Global Registry of Acute Coronary Events (GRACE), and statistical summaries of U.S. hospital discharges prepared by the AHA. In patients with STE ACS, in-hospital death rates are approximately 4.6%, while it is lower, 2.2%, for patients with NSTE ACS.[8] Patients with STE MI who are treated with reperfusion therapy, either fibrinolytics or primary PCI, have lower mortality rates than patients treated without reperfusion. Reperfusion rates and mortality rates are higher in the elderly and women. For example, the mortality rate is 19% in elderly patients who were eligible for reperfusion therapy but did not receive it compared with 10.5% in those that did.[8–10] In women, the mortality rate is 18% in those eligible for but who did not receive reperfusion therapy compared with 9.3% in those who did.[8–10] In the first year following MI, 23% of women and 18% of men will die, most from recurrent infarction.[1] At 1 year, rates of mortality and reinfarction are similar between STE and NSTE MI.[10]

The rate of developing heart failure during hospitalization for ACS is declining rapidly. Compared with data from 1999, the 2006 incidence of in-hospital heart failure in patients with STE MI declined from 19.5% to 11% and that for patients with NSTE ACS declined from 13% to 6.1%.[9] In-hospital death rates for patients who present with or develop heart failure are more than threefold higher than for those who do not.[8]

Because reinfarction and death are major outcomes following ACS, therapeutic strategies to reduce morbidity and mortality, particularly use of coronary angiography, revascularization, and pharmacotherapy, will have a significant impact on the social and economic burden of CHD in the United States.

ETIOLOGY

In this section we will discuss the formation of atherosclerotic plaques, the underlying cause of coronary artery disease (CAD) and ACS in most patients. The process of atherosclerosis starts early in life. Although atherosclerosis was once considered only a disease of cholesterol excess, it is now clear that inflammation also plays a central role in the genesis, progression, and complication of this disease.[11] In its earliest stage, endothelial dysfunction, the induction and/or repression of several genes, occurs in response to sheer stress of the blood flowing over the atherosclerotic plaque on the endothelial lining of the artery. In response to gene induction and repression, the endothelial cells decrease the synthesis of nitric oxide, increase the oxidation of lipoproteins and facilitate their entry into the arterial wall, promote the adherence of monocytes to the vessel wall and deposition of extracellular matrix, cause smooth muscle cell proliferation, and release local vasoconstrictor and prothrombotic substances into the blood, each with subsequent inflammatory response.[11] Taken together, all these factors contribute to the evolution of endothelial dysfunction to the formation of fatty streaks in the coronary arteries and eventually to atherosclerotic plaques. Therefore, the endothelium serves as an important autocrine and paracrine organ in the development of atherosclerosis.

A number of factors are directly responsible for the development and progression of endothelial dysfunction and atherosclerosis, including hypertension, age, male gender, tobacco use, diabetes mellitus, obesity, and dyslipidemias.[1]

PATHOPHYSIOLOGY

SPECTRUM OF ACS

Acute coronary syndromes is a term that includes all clinical syndromes compatible with acute myocardial ischemia resulting from an imbalance between myocardial oxygen demand and supply. In contrast to stable angina, an ACS results primarily from diminished myocardial blood flow secondary to an occlusive or partially occlusive coronary artery thrombus. ACSs are classified according to electrocardiographic changes into STE MI and NSTE ACS, which includes NSTE MI and UA (Fig. 24–1).[2–6,12,13] For patients presenting with suspected ACS, the percentage of patients diagnosed with STE MI varies by registry or database but is approximately 30%, while 31% are diagnosed with NSTE MI, 26% with UA, and 12% with another cardiac or noncardiac condition.[14] NSTE MI differs from UA in that ischemia is severe enough to produce myocardial necrosis, resulting in the release of a detectable amount of biochemical markers, mainly troponins I or T, and creatine kinase (CK) myocardial band (MB) from the necrotic myocytes, into the bloodstream.[6] The clinical significance of serum biochemical markers is discussed in more detail in the section entitled "Biochemical Markers" of this chapter. Following an STE MI, pathologic Q waves are seen frequently on the electrocardiogram (ECG), whereas such an ECG manifestation is seen less commonly in patients with NSTE MI.[2,6] The presence of Q waves usually indicates transmural MI.

PLAQUE RUPTURE AND CLOT FORMATION

1 The predominant cause of ACS in more than 90% of patients is atheromatous plaque rupture, fissuring, or erosion of an unstable atherosclerotic plaque. Plaques that encompass less than 50% of the coronary lumen are more likely to rupture than those that occlude 70% to 90% of the coronary artery.[6] Such stable 70% to 90% stenoses of the coronary artery are characteristic of stable angina and tend to have a small lipid core, a thick fibrous cap, more calcification and less compensatory enlargement.[15] Plaques that are more susceptible to rupture are characterized by an eccentric shape, a thin fibrous cap (particularly in the shoulder region of the plaque), large fatty core, a high content in inflammatory cells, such as macrophages and lymphocytes, limited amounts of smooth muscle, and significant compensatory enlargement. Compensatory enlargement is the growth of the lesion pushing the vessel outward rather than the growth of plaque inward. Therefore, compensatory enlargement may result in an underestimation of the atherosclerotic stenosis as measured by coronary angiography. Inflammatory cells promote the thinning of the fibrous cap through the release of proteolytic enzymes, particularly matrix metalloproteinases.[11]

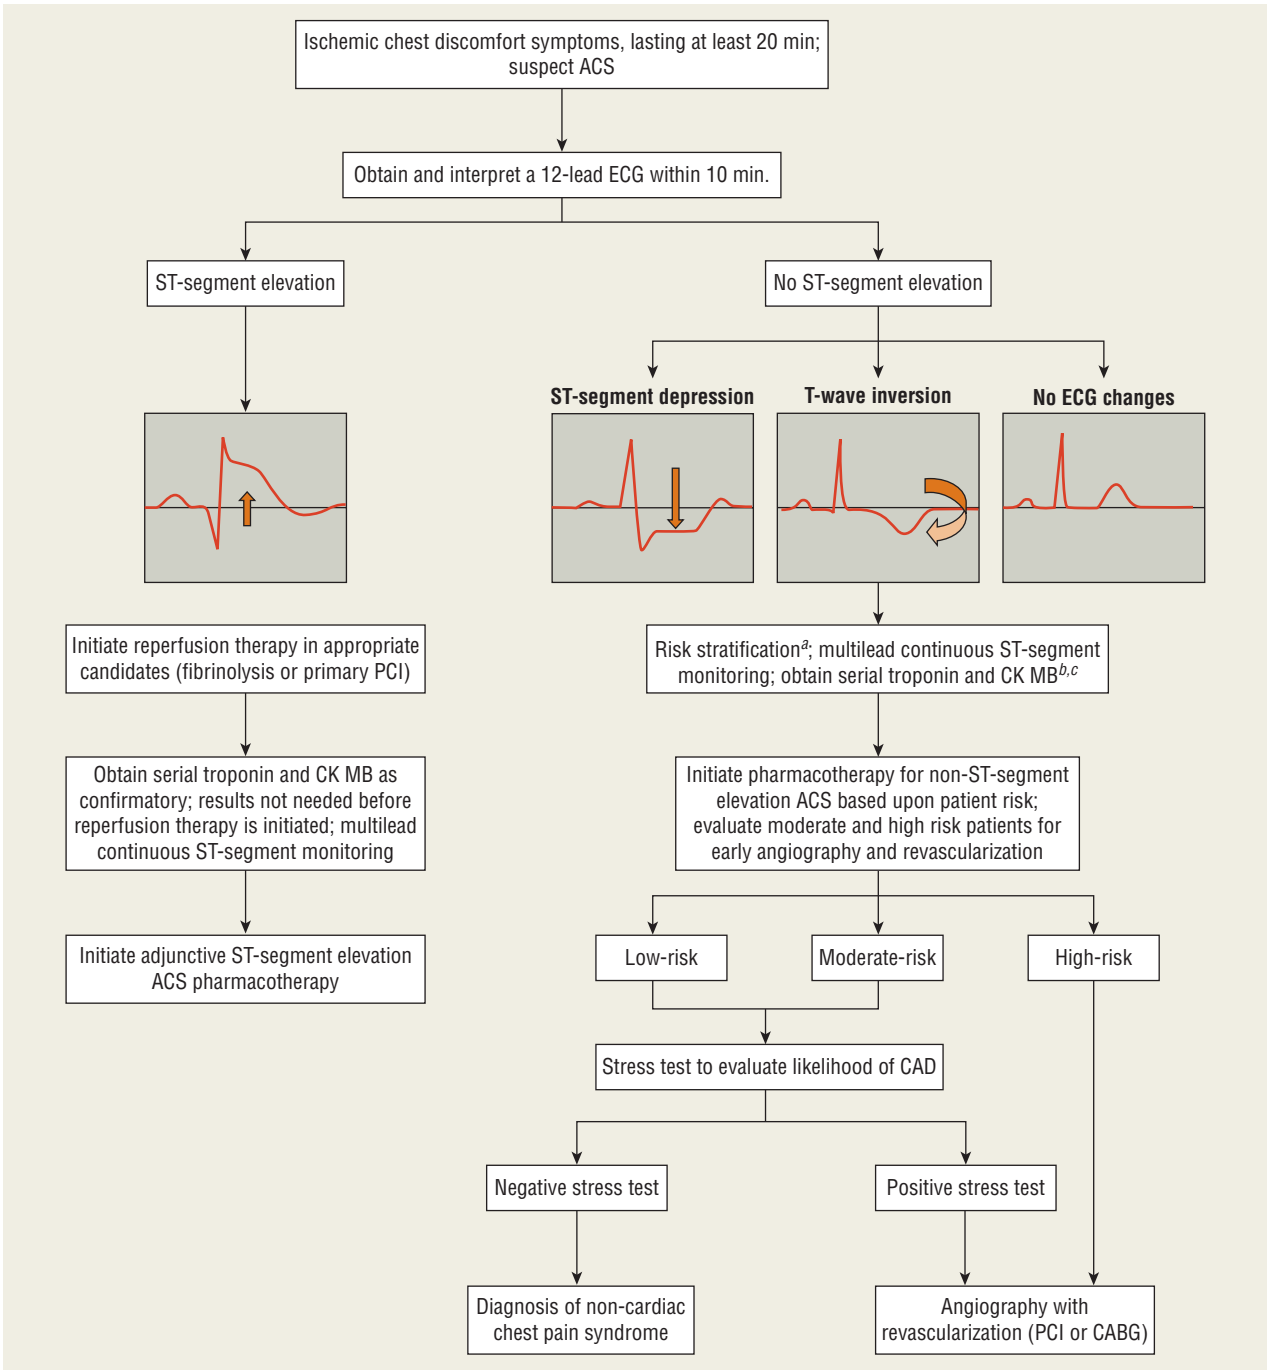

FIGURE 24-1. Evaluation of the Acute Coronary Syndrome Patient. (ACS, acute coronary syndrome; CABG, coronary artery bypass graft surgery; CAD, coronary artery disease; CK, creatine kinase; ECG, electrocardiogram; PCI, percutaneous coronary intervention.) [a]As described in Table 24–2. [b]Positive means above the MI decision limit. [c]Negative means below the MI decision limit. *(Reproduced with permission from: Spinler SA. Acute coronary syndromes. Pharmacotherapy self-assessment program Book 1, 6th ed., Cardiology. Kansas City: American College of Clinical Pharmacy; 2007. p. 59–83.)*

Following plaque rupture, a partially occlusive or completely occlusive thrombus, a clot, forms on top of the ruptured plaque. The thrombogenic contents of the plaque are exposed to blood elements. Exposure of exposed subendothelial collagen and tissue factor via shear forces promote platelet adhesion to the site of injury via binding of platelet glycoprotein (GP) Ib to von Willebrand factor. This binding interaction integrates signals that cause platelets to become activated—undergoing a shape change, as well as synthesizing and releasing thromboxane A_2 (TXA_2), adenosine diphosphate (ADP), and vasoactive and other prothrombotic substances from dense α-granules. Furthermore, during platelet activation, ADP binds to the platelet $P2Y_1$ and $P2Y_{12}$ receptors, and $P2Y_{12}$ binding promotes a conformational change in the GP IIb/IIIa surface receptors of platelets, increasing their affinity for fibrinogen that results in cross-linking of platelets to each other through fibrinogen bridges. This is considered the final common pathway of platelet aggregation. Additionally, ADP binding to the $P2Y_{12}$ receptor promotes amplification of platelet aggregation and recruitment of other platelets to the site of injury by promoting release of other platelet aggregation agonists such as serotonin, thrombin, TXA_2, and epinephrine. Inclusion of platelets gives the clot a white appearance.

Simultaneously, the extrinsic coagulation cascade pathway is activated as a result of exposure of blood components to the thrombogenic lipid core and endothelium, which are rich in tissue factor.

This leads to the production of thrombin (factor IIa), which converts fibrinogen to fibrin through enzymatic activity. Fibrin stabilizes the clot and traps red blood cells, which give the clot a red appearance. Thrombin also serves as a potent platelet aggregation agonist and promotes platelet recruitment to the site. Clotting factors assemble on the anionic activated platelet surface promoting more thrombin generation, thereby amplifying both coagulation and platelet aggregation. Therefore, the clot is composed of both cross-linked platelets and fibrin strands. While a patient with an ACS more commonly presents with a single, ruptured atherosclerotic plaque in one major coronary artery, they may present with more than one ruptured plaque and multiple active lesions in more than one coronary artery, which predispose the patient to a worse prognosis.[11]

A thrombus containing more platelets than fibrin, or a "white" clot, generally produces an incomplete occlusion of the coronary lumen and is more common in NSTE ACS. For patients presenting with an STE MI, the vessel generally is completely occluded by a "red" clot that contains larger amounts of fibrin and red blood cells but a smaller amount of platelets compared with a "white" clot.[2] As will be discussed later in this chapter in the section on treatment, the composition of the clot influences the selection of the combinations of antithrombotic agents used in STE and NSTE ACS. Finally, myocardial ischemia can result from the downstream embolization of microthrombi and produce ischemia with eventual necrosis.[2]

VENTRICULAR REMODELING FOLLOWING AN ACUTE MI

Ventricular remodeling is a process that occurs in several cardiovascular conditions, including left ventricular (LV) heart failure, and follows an MI. It is characterized by changes in the size, shape, and function of the left ventricle of both the infarcted area and the remaining ventricle, and it ultimately leads to cardiac failure.[16] Because heart failure represents one of the principal causes of mortality and morbidity following an MI, preventing ventricular remodeling is an important therapeutic goal.[16]

Many factors contribute to ventricular remodeling, including neurohormonal factors (e.g., activation of the renin–angiotensin–aldosterone and sympathetic nervous systems), hemodynamic factors, mechanical factors, changes in gene expression and modifications in myocardial matrix metalloproteinase activity and their inhibitors.[17,18] This process affects both cardiomyocytes (cardiomyocyte hypertrophy, loss of cardiomyocytes) and the extracellular matrix (increased interstitial fibrosis), thereby promoting both systolic and diastolic dysfunction.[18]

Angiotensin-converting enzyme (ACE) inhibitors, β-blockers, and aldosterone antagonists are all agents that slow down or reverse ventricular remodeling through neurohormonal blockage and/or through improvement in hemodynamics (decreasing preload or afterload).[16] These agents also improve survival and will be discussed in more detail in subsequent sections of this chapter describing treatment and secondary prevention. This underlines the importance of the remodeling process and the urgency of preventing, halting, or reversing it for patients who have experienced an MI.

COMPLICATIONS

This chapter will focus on management of the uncomplicated ACS patient. However, it is important for clinicians to recognize complications of MI because such patients have increased mortality. The most serious complication is cardiogenic shock, occurring in approximately 5% to 6% of patients presenting with STE MI and less than 2% of those presenting with NSTE ACS.[14] Mortality in cardiogenic shock patients with MI is high, approaching 60%.[8] Other complications that may result from MI are heart failure, valvular dysfunction, ventricular and atrial tachyarrhythmias, bradycardia, heart block, pericarditis, stroke secondary to LV thrombus embolization, venous thromboembolism, and LV free wall rupture.[19] In fact, more than one-quarter of MI patients die, presumably from ventricular fibrillation, prior to reaching the hospital.[20]

TABLE 24-1 Presentation of Acute Coronary Syndromes

General
- The patient typically is in acute distress and may develop or present with cardiogenic shock.

Symptoms
- The classic symptom of ACS is midline anterior chest discomfort. Accompanying symptoms may include arm, back or jaw pain, nausea, vomiting, or shortness of breath.
- Patients less likely to present with classic symptoms include elderly patients, diabetic patients, and women.

Signs
- No signs are classic for ACS.
- However, patients with ACS may present with signs of acute heart failure, including jugular venous distension, rales, and S_3 sound on auscultation.
- Patients may present with arrhythmias and therefore may have tachycardia, bradycardia, or heart block.

Laboratory tests
- Troponin I or T and creatine kinase MB are measured.
- Blood chemistry tests are performed with particular attention to potassium and magnesium, which may affect heart rhythm, and glucose, which when elevated places the patient at higher risk for morbidity and mortality.
- Serum creatinine level is measured to identify patients who may need dosing adjustments for some pharmacotherapy and patients who are at high risk for morbidity and mortality.
- Baseline complete blood count and coagulation tests (activated partial thromboplastin time and international normalized ratio) should be obtained because most patients will receive antithrombotic therapy, which increases the risk for bleeding.
- Fasting lipid panel is obtained.

Other diagnostic tests
- The 12-lead electrocardiogram is the first step in management. Patients are risk stratified into two groups: ST-segment elevation ACS and suspected non–ST-segment elevation ACS.
- During hospitalization, measurement of left ventricular function, such as an echocardiogram, is performed to identify patients with low ejection fractions (<40%) who are at high risk for death following hospital discharge.
- Selected low-risk patients may undergo early stress testing.

ACS, acute coronary syndrome.

CLINICAL PRESENTATION

The key points in clinical presentation of the patient with ACS are described in Table 24–1.

SYMPTOMS AND PHYSICAL EXAMINATION FINDINGS

The classic symptom of an ACS is midline anterior anginal chest discomfort, most often either at rest, severe new-onset, or increasing angina that is at least 20 minutes in duration. The chest discomfort may radiate to the shoulder, down the left arm, to the back, or to the jaw. Associated symptoms that may accompany the chest discomfort include nausea, vomiting, diaphoresis, or shortness of breath. Typically, patients with STE MI present with unremitting chest discomfort. Patients with NSTE ACS may present with either (1) rest angina, (2) new onset (less than 2 months) angina, or (3) angina that is increasing in either frequency, duration, or intensity. All healthcare professionals should review these warning symptoms

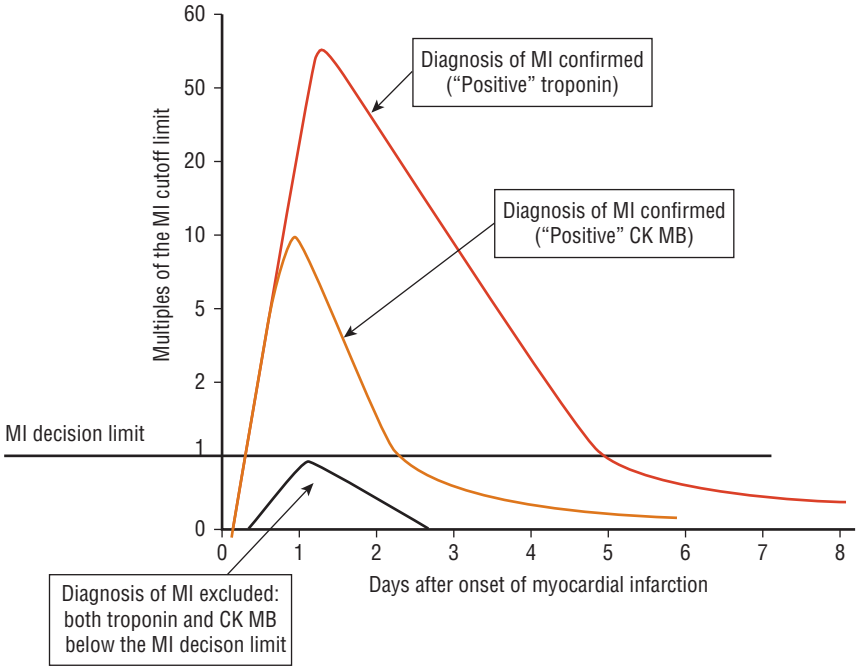

FIGURE 24-2. Biochemical markers in suspected acute coronary syndrome.

with patients at high risk for CHD. On physical examination, no specific features are indicative of ACS.

TWELVE-LEAD ELECTROCARDIOGRAM (ECG)

❸ There are key features of a 12-lead ECG that identify and risk stratify a patient with an ACS. Within 10 minutes of presentation to an emergency department with symptoms of ischemic chest discomfort (or preferably prehospital), a 12-lead ECG should be obtained and interpreted. If available, a prior 12-lead ECG should be reviewed to identify whether the findings on the current ECG are new or old, with new findings being more indicative of an ACS. Key findings on review of a 12-lead ECG that indicate myocardial ischemia or MI are ST-segment elevation, ST-segment depression, and T-wave inversion (Fig. 24–1).[13] ST-segment and/or T-wave changes in contiguous leads help to identify the location of the coronary artery that is the cause of the ischemia or infarction. In addition, the appearance of a new left bundle branch block accompanied by chest discomfort is highly specific for acute MI. About 40% of patients diagnosed with MI present with ST-segment elevation on their ECG, with the remainder having ST-segment depression, T-wave inversion, or in some instances, no ECG changes.[21] Some parts of the heart are more "electrically silent" than others, and myocardial ischemia may not be detected on a surface ECG. Therefore, it is important to review findings from the ECG in conjunction with biochemical markers of myocardial necrosis, such as troponin I or T, and other risk factors for CHD to determine the patient's risk for experiencing a new MI or having other complications.

BIOCHEMICAL MARKERS

❹ Biochemical markers of myocardial cell death are important for confirming the diagnosis of MI. *Evolving MI* is defined by the ACC as "typical rise and gradual fall (troponin) or more rapid rise and fall (CK-MB) of biochemical markers of myocardial necrosis."[22] Troponin and CK-MB rise in the blood following the onset of complete coronary artery occlusion subsequent myocardial cell death. Their time course is depicted in Figure 24–2. Typically, blood is obtained from the patient at least two times, once in the emergency department and again in 6 to 9 hours, in order to measure troponin and CK-MB.[23] A single measurement of a biochemical marker is not adequate to exclude a diagnosis of MI because up to 15% of the values that were below the level of detection initially (a negative test) are above the level of detection (a positive test) in the subsequent hours. An MI is identified if at least one troponin value is greater than the MI decision limit, defined as above the 99th percentile of a reference population (set by the hospital laboratory and dependent upon the assay used) with a typical rise or fall.[23] If a troponin test is not available, an increase CK-MB (above the 99th percentile of a reference population with a cut-off value dependent upon assay), may also be used to make the diagnosis of MI. These are termed *positive* biochemical markers for MI. While troponins and CK-MB appear in the blood within 6 hours of infarction, troponins stay elevated in the blood for 7 to 14 days, whereas CK-MB returns to normal values within 48 hours. If early reinfarction is suspected, blood should be drawn and troponin and CK-MB repeated. Reinfarction is diagnosed when the CK-MB or troponin are elevated at least 20% above the previous value (as well as above the 99th percentile of the reference population).[23] Biochemical markers, such as troponin measurements, that are below the hospital laboratories reference range are termed *negative* and the diagnosis of MI is excluded.

RISK STRATIFICATION

Patient signs and symptoms, past medical history, ECG, and troponin or CK-MB determinations are used to stratify patients into low, medium, or high risk of death, initial MI, reinfarction, or likelihood of failing pharmacotherapy and needing urgent coronary angiography and PCI (Fig. 24–1). Patients with STE MI are at the highest risk of death. In a report from the Global Registry of Acute Coronary Events (GRACE) of almost 30,000 patients from 2001 to 2007, in-hospital mortality rates were 6.2% for STE MI, 2.9% for NSTE MI, and 1.7% for UA.[14] Initial treatment of STE MI should proceed without evaluation of the troponin or CK-MB levels because these patients have a greater than 97% chance of having an MI subsequently diagnosed with biochemical markers. The

ACC/AHA as well as The Joint Commission defines a target time to initiate reperfusion treatment for STE MI within 30 minutes of hospital presentation for fibrinolytics and within 90 minutes or less from presentation for primary PCI.[6,23,24] The sooner the infarct-related coronary artery is opened for these patients, the lower is their mortality, and the greater is the amount of myocardium that is preserved.[14,25,26] The 2009 STE MI guideline update recommends that patients be evaluated for interhospital transfer for PCI if they present to a hospital without a cardiac catheterization laboratory and primary PCI capability as an alternative to fibrinolysis.[5] Regionalized systems of STE MI care are encouraged.[5,27]

While all patients should be evaluated for reperfusion therapy, not all patients may be eligible. Indications and contraindications for fibrinolytic therapy as well as eligibility criteria for primary PCI are described in the treatment section of this chapter. In the United States in 2006, 66% of patients presenting with STE MI met eligibility for reperfusion therapy. Among all eligible patients, only 70.8% received reperfusion therapy in 2006.[14] Since 2004, the frequency of primary PCI has exceeded the frequency of fibrinolysis such that in 2006, 43.2% of eligible patients presenting with STE MI underwent primary PCI, while 27.6% received fibrinolysis.[14] Most of those not eligible for reperfusion therapy present more than 12 hours after the onset of symptoms, outside of the eligibility window.[14,28,29] In addition, fewer than 50% of patients with MI in the United States present to hospitals that are equipped to perform primary PCI, and approximately 5% to 6% of patients present with at least one contraindication to fibrinolysis.[21,28,29] Unfortunately, 28% of patients *eligible* for reperfusion therapy with either fibrinolysis or primary PCI do not receive it, suggesting there is still a need for more thorough patient evaluation and treatment triage.[14]

If patients are not eligible for reperfusion therapy or interhospital transfer, additional pharmacotherapy for STE patients should be initiated in the emergency department, and the patient should be transferred to a coronary intensive care unit (Fig. 24–1).[30]

Risk stratification of the patient with NSTE ACS is more complex because in-hospital outcomes for this group of patients vary, with reported rates of death of 0% to 12%, reinfarction of 0% to 3%, and recurrent severe ischemia of 5% to 20%.[31] Not all patients presenting with suspected NSTE ACS will even have CAD. Some will be diagnosed eventually with nonischemic chest discomfort. Additional information regarding risk stratification of NSTE ACS is presented in the section general approach to treatment.

TREATMENT

Acute Coronary Syndromes

DESIRED OUTCOMES

The short-term goals of treatment for the ACS patient are

1. Early restoration of blood flow to the infarct-related artery to prevent infarct expansion (in the case of MI) or prevent complete occlusion and MI (in UA)
2. Prevention of death and other MI complications
3. Prevention of coronary artery reocclusion with reinfarction
4. Relief of ischemic chest discomfort
5. Resolution of ST-segment and T-wave changes on ECG

GENERAL APPROACH TO TREATMENT

2 Selecting evidence-based therapies described in the ACC/AHA guidelines for patients without contraindications results in lower mortality.[32–34] General treatment measures for all STE MIs and high- and intermediate-risk NSTE ACS patients include admission to hospital, oxygen administration (if oxygen saturation is low, <90%), continuous multilead ST-segment monitoring for arrhythmias and ischemia, glycemic control, frequent measurement of vital signs, bed rest for 12 hours in hemodynamically stable patients, avoidance of Valsalva maneuver (prescribe stool softeners routinely), and pain relief.

Because risk varies and resources are limited, it is important to triage and treat patients according to their risk category. Initial approaches to treatment of the STE and NSTE ACS patient are outlined in Figure 24–1.[2–6,12] Patients with STE MI are at high risk of death, and efforts to reestablish coronary perfusion should be initiated immediately. Reperfusion therapy should be considered immediately and adjunctive pharmacotherapy initiated.[6]

Features identifying low-, moderate-, and high-risk NSTE ACS patients are described in Table 24–2.[2,35–37] Patients at low risk for death, initial MI or recurrent MI or for refractory angina needing urgent coronary artery revascularization typically are

TABLE 24-2 Risk Stratification for ACS[35–37]

TIMI risk score for NSTE ACS

One point is assigned for each of the seven medical history and clinical presentation findings. The point total is calculated and the patient is assigned a risk for experiencing the composite endpoint of death, myocardial infarction, or urgent need for revascularization as follows:

- Age ≥ 65 years
- 3 or more CHD risk factors: smoking, hypercholesterolemia, hypertension, diabetes mellitus, family history of premature CHD death/events
- Known CAD (≥50% stenosis of at least one major coronary artery on coronary angiogram)
- Aspirin use within the past 7 days
- 2 or more episodes of chest discomfort within the past 24 hrs
- ST-segment depression ≥0.5 mm
- Positive biochemical marker for infarction

High-risk	Medium-risk	Low-risk
TIMI risk score 5–7 points	TIMI risk Score 3–4 points	TIMI risk score 0–2 points

TIMI risk score	Mortality, MI, or severe recurrent ischemic requiring urgent target vessel revascularization
0/1	4.7%
2	8.3%
3	13.2%
4	19.9%
5	26.2%
6/7	40.9%

GRACE risk factors for increased mortality and the composite of death or MI in ACS

- Signs and symptoms of heart failure
- Low systolic blood pressure
- Elevated heart rate
- Older age
- Elevated serum creatinine
- Baseline risk factors on clinical evaluation: cardiac arrest at admission, ST-segment deviation, elevated troponin
- A high-risk patient is defined as a GRACE risk score of >140 points

TIMI = Thrombolysis in Myocardial Infarction; CAD = coronary artery disease; MI = myocardial infarction; GRACE = Global Registry of Acute Coronary Events.

An online calculator for the GRACE Risk Model is available at http://www.outcomes-umassmed.org/externalwindow.cfm?URL=http://www.outcomes.org/grace/acs_risk/acs_risk.html&Link=http://www.outcomes-umassmed.org/grace/acs_risk.cfm&DeptName=Center%20for%20Outcomes%20Research (Accessed March 22, 2010).

evaluated in the emergency department, where serial biochemical marker tests are obtained, and if they are negative, the patient may be admitted to a general medical floor with ECG telemetry monitoring for ischemic changes and arrhythmias, undergo a noninvasive stress test, or be discharged from the emergency department. Moderate- and high-risk patients are admitted to a coronary intensive care unit, an intensive care step-down unit, or a general medical floor in the hospital depending on the patient's symptoms and perceived level of risk. High-risk patients should undergo early coronary angiography (within 12 to 24 hours) and revascularization (with PCI or CABG) if a significant coronary artery stenosis is found[5] (Fig. 24–1 and Table 24–2). Moderate-risk patients with positive biochemical markers for infarction typically also will undergo angiography and revascularization during hospital admission. Moderate-risk patients with negative biochemical markers for infarction also may undergo angiography and revascularization or first undergo a noninvasive stress test, with only select patients with a positive stress test proceeding to angiography. Following risk stratification, pharmacotherapy for NSTE ACS is initiated.

NONPHARMACOLOGIC THERAPY

Primary PCI for STE ACS

5 Either fibrinolysis or immediate primary PCI is the treatment of choice for reestablishing coronary artery blood flow for patients with STE ACS when the patient presents within 3 hours of symptom onset and both options are available at the institution. For primary PCI, the patient is taken from the emergency department to the cardiac catheterization laboratory and undergoes coronary angiography with either balloon angioplasty or placement of a bare-metal or drug-eluting intracoronary stent. Additional details regarding angioplasty and intracoronary stenting are provided in Chap. 23. Results from a meta-analysis of trials comparing fibrinolysis with primary PCI indicate a lower mortality rate with primary PCI.[38] One reason for the superiority of primary PCI compared with fibrinolysis is that more than 90% of occluded infarct-related coronary arteries are opened with primary PCI compared with less than 60% of coronary arteries with currently available fibrinolytics.[4,6] In addition, the stroke [including intracranial hemorrhage (ICH)] and major bleeding risks from primary PCI are lower than following fibrinolysis.[4,6] An invasive strategy of primary PCI is generally preferred for patients presenting to institutions with skilled interventional cardiologists and a catheterization laboratory immediately available, for patients with cardiogenic shock, for patients with contraindications to fibrinolytics, and for patients presenting with symptom onset greater than 3 hours.[6] Patients presenting to a facility that is not capable of performing primary PCI may receive fibrinolysis or be immediately transferred to another hospital for primary PCI.[5] Patients best suited for transfer are those presenting more than 4 hours after symptom onset and those at high-risk for bleeding with fibrinolysis. The ACC/AHA guidelines encourage the formation of systems of care for rapid STE MI reperfusion treatment.[5] A quality performance measure in the care of patients with STE MI is the time from hospital presentation to the time that the occluded artery is opened with PCI. This "door-to-primary PCI time" should be ≤90 minutes (Table 24–3).[6,12,23] In 2006, the median time to primary PCI in the United States was 79 min for nontransferred patients and 139 minutes for transferred patients.[10] In 2006, only 54% of patients met the performance measure target of ≤90 minutes.[10] However more recent data from 2008 suggested that more than 75% of nontransferred patients had door-to-primary PCI times of ≤90 minutes, suggesting that efforts such as the Door to Balloon (D2B) Time Alliance educational materials and tools available on line have been successful.[39] Unfortunately, most hospitals do not have interventional cardiology services capable of performing primary PCI 24 hours a day.

Patients in whom fibrinolysis is not successful (as determined by persistent rest ischemic symptoms), as well as those receiving fibrinolysis but at continued high risk for death (including patients in cardiogenic shock patients with life-threatening ventricular arrhythmias or signs of ischemia on stress testing following MI), should be transferred to a hospital capable of cardiac catheterization and undergo angiography and PCI as early as possible (Fig. 24–1).[3–6] A randomized study established that "rescue" PCI for failed fibrinolysis was superior to repeated fibrinolytic administration or conservative management, resulting in lower cardiac and cerebrovascular events.[40] The strategy of routine angiography and revascularization in all STE patients later during hospitalization was controversial for more than a decade, but data from the Occluded Artery Trial (OAT) demonstrated that routine angiography followed by PCI in stable patients 3 to 28 days post-MI, without recurrent unprovoked ischemia or ischemia induced by stress testing, is not beneficial in reducing mortality or heart failure

TABLE 24-3 ACC/AHA 2008 Quality Performance Measures and Test Measures for Acute Coronary Syndrome[12]

Quality Performance Measure	Test Measure
Aspirin at arrival	LDL-C Assessment
Aspirin prescribed at discharge	Excessive initial heparin dose
β-blocker prescribed at hospital discharge	Excessive initial LMWH dose
Statin prescribed at hospital discharge	Excessive initial abciximab dose
ACE inhibitor or ARB for LVD prescribed at discharge	Excessive initial eptifibatide dose
Evaluation of LV function	Excessive initial tirofiban dose
Time to fibrinolytic therapy for patients with STE MI or LBBB	Presence of an anticoagulation dosing protocol for ACS (structural measure)
Time to PCI for patient with STE MI	Presence of an anticoagulant medication error tracking system
Time from ED arrival to ED discharge when transferring for STE MI PCI to another hospital	
Time from ED arrival at STE MI referral facility to PCI at receiving facility	
Percent of eligible patients with STE MI or LBBB receiving reperfusion therapy	
Smoking cessation counseling	
Cardiac rehabilitation referral	

ACE = angiotensin converting enzyme; ACS = acute coronary syndrome; ARB = angiotensin receptor blocker; ED = emergency department; LBBB = left bundle branch block; LDL-C = low-density lipoprotein cholesterol; LMWH = low-molecular weight heparin; LVD = left ventricular dysfunction; PCI = percutaneous coronary intervention; STE MI = ST-segment elevation myocardial infarction.

and may increase the risk of recurrent MI.[41] Therefore, routine *late* restoration of antegrade coronary artery blood flow in patients not at high risk should not be performed.[5]

Percutaneous Coronary Intervention in Non-ST-Segment Elevation ACS

6 The most recent ACC/AHA PCI and STEMI practice guideline update recommends early coronary angiography within 12 hours following hospital presentation and subsequent revascularization for patients with suitable coronary anatomy with either PCI and bare-metal or drug-eluting stent placement or CABG as an early treatment for high-risk NSTE ACS patients, and that such an approach be considered for patients not at high risk.[5] Several clinical trials support an "early invasive strategy" with PCI or CABG versus a "medical stabilization management strategy" whereby coronary angiography with revascularization is reserved for patients with symptoms refractory to pharmacotherapy and patients with signs of ischemia on stress testing (Fig. 24–1).[5,12] An early invasive approach results in a lower rate of refractory angina during hospital admission and over the first year, as well as a lower frequency of MI at 5 years, but an increased frequency of minor bleeding related to the procedure.[42] An early invasive strategy is also less costly than the conservative medical stabilization approach.[43]

Additional Testing and Risk Stratification

At some point during hospitalization but prior to discharge, patients with MI should have their LV function evaluated for risk stratification.[1,6,23] The most common way LV function is measured is using an echocardiogram to calculate the patient's LV ejection fraction (LVEF). LV function is the single best predictor of mortality following MI. Patients with LVEFs of less than 40% are at highest risk of death. Patients with an estimated survival of more than 1 year who are receiving medical therapy for secondary MI prevention and are in New York Heart Association (NYHA) functional Class II or III who have an LVEF <35% or those in NYHA functional class I who have an LVEF of <30% at 40 days following MI should receive an implantable cardioverter defibrillator (ICD) for primary prevention of sudden cardiac death.[44] The Multicenter Automatic Defibrillator Implantation II trial (MADIT) demonstrated a 29% reduction in mortality for patients with a history of MI, low LVEFs, and no history of symptomatic ventricular arrhythmias who received prophylactic implantation of an ICD.[45] Additional discussion of the role of ICDs in the management of high-risk patients and those with ventricular arrhythmias may be found in Chap. 25.

Predischarge stress testing may be performed in moderate- or low-risk patients in order to determine which patients would benefit from coronary angiography to establish the diagnosis of CAD and also for patients following MI to predict intermediate and long-term risk of recurrent MI and death[2,46] (Fig. 24–1). In most cases, patients with a positive stress test indicating coronary ischemia will then undergo coronary angiography and subsequent revascularization of significantly occluded coronary arteries. Exercise stress testing, most often with the addition of a radionuclide imaging agent, is preferred over nonpharmacologic stress testing because it evaluates the workload achieved with exercise as well as the occurrence of ischemia. If a patient has a negative exercise stress test for ischemia, the patient is at low risk for subsequent CHD events. Therefore, exercise stress testing has high negative predictive value. Additional discussion of the types of stress testing may be found in Chap. 23.

Patients admitted for ACS should have a fasting lipid panel drawn within the first 24 hours of hospitalization with statins the preferred agents to achieve a target low-density lipoprotein (LDL) cholesterol of less than 100 mg/dL and ideally <70 mg/dL.[3]

EARLY PHARMACOTHERPY FOR ST-SEGMENT ELEVATION ACS

Pharmacotherapy for early treatment of STE MI is outlined in Figure 24–3.[3–6] 7 According to the ACC/AHA STE MI practice guidelines and updates, early pharmacotherapy of STE MI should include intranasal oxygen (if oxygen saturation is <90%), sublingual (SL) nitroglycerin (NTG), aspirin, an anticoagulant, and fibrinolysis in eligible candidates. Morphine is administered to patients with refractory angina as an analgesic and a venodilator that lowers preload, but it does not reduce mortality.[47] These agents should be administered early, while the patient is still in the emergency department. A thienopyridine, either prasugrel or clopidogrel, should be administered for patients undergoing PCI, while only clopidogrel is recommended for patients receiving fibrinolytics and those not undergoing reperfusion therapy.[5] An ACE inhibitor should be started within 24 hours of presentation, particularly for patients with an LVEF ≤40%, signs of heart failure (HF) or an anterior wall MI, in the absence of contraindications. Intravenous (IV) NTG, β-blockers, and an aldosterone antagonist should be administered in select patients. A statin should be initiated prior to hospital discharge for patients with an LDL cholesterol of >100 mg/dL.[3,6] Dosing and contraindications for SL and IV NTG, aspirin, β-blockers, anticoagulants, ACE inhibitors, aldosterone antagonists, and fibrinolytics are listed in Table 24–4.[3–6,12]

Fibrinolytic Therapy

Administration of a fibrinolytic agent is indicated for patients with STE MI presenting to hospital within 12 hours of the onset of chest discomfort (that has persisted for at least 20 minutes) who have at least 1 mm of ST-segment elevation in two or more contiguous ECG leads (suggestive of infarct location) or a new left bundle branch block.[6] Fibrinolytic therapy should also be considered for patients presenting within 12–24 hours who have persistent symptoms of ischemia and at least 1 mm of STE in two or more contiguous leads.[6] The mortality benefit of fibrinolysis is highest with early administration and diminishes after 12 hours. Fibrinolytic therapy is preferred over primary PCI for patients presenting within 3 hours of symptom onset where there is a delay to primary PCI because of a delay in access to a cardiac catheterization laboratory or a delay in obtaining patient vascular access that would result in a "door-to-primary PCI" delay that would be greater than 90 minutes.[3] Contraindications to fibrinolysis include a history of hemorrhagic stroke (at any time), history of ischemic stroke within the 3 months, active internal bleeding, known intracranial neoplasm, suspected aortic dissection.[6] It is not necessary to obtain the results of biochemical markers before initiating fibrinolytic therapy. Because administration of fibrinolytics results in clot lysis, patients at high risk for major bleeding, including ICH, have either relative or absolute contraindications. Patients presenting with an absolute contraindication likely will not receive fibrinolytic therapy, and primary PCI is preferred. Patients with a relative contraindication may receive fibrinolytic therapy if the perceived risk of death from the MI is higher than the risk of major hemorrhage. For every 1,000 patients with anterior wall MI, treatment with fibrinolysis saves 37 lives compared with placebo. For patients with inferior wall MI, who generally have smaller MIs and are at lower risk of death, treatment with fibrinolysis saves 8 lives per 1,000 patients treated.[25]

Fibrinolytic therapy is controversial for patients older than 75 years of age. More than 60% of all MI deaths occur in this group. Benefit, in terms of absolute mortality reduction compared with placebo, varies from approximately 1% to 9%, with some observational studies suggesting higher mortality in the very elderly treated with fibrinolysis compared with no fibrinolysis. Stroke rates also

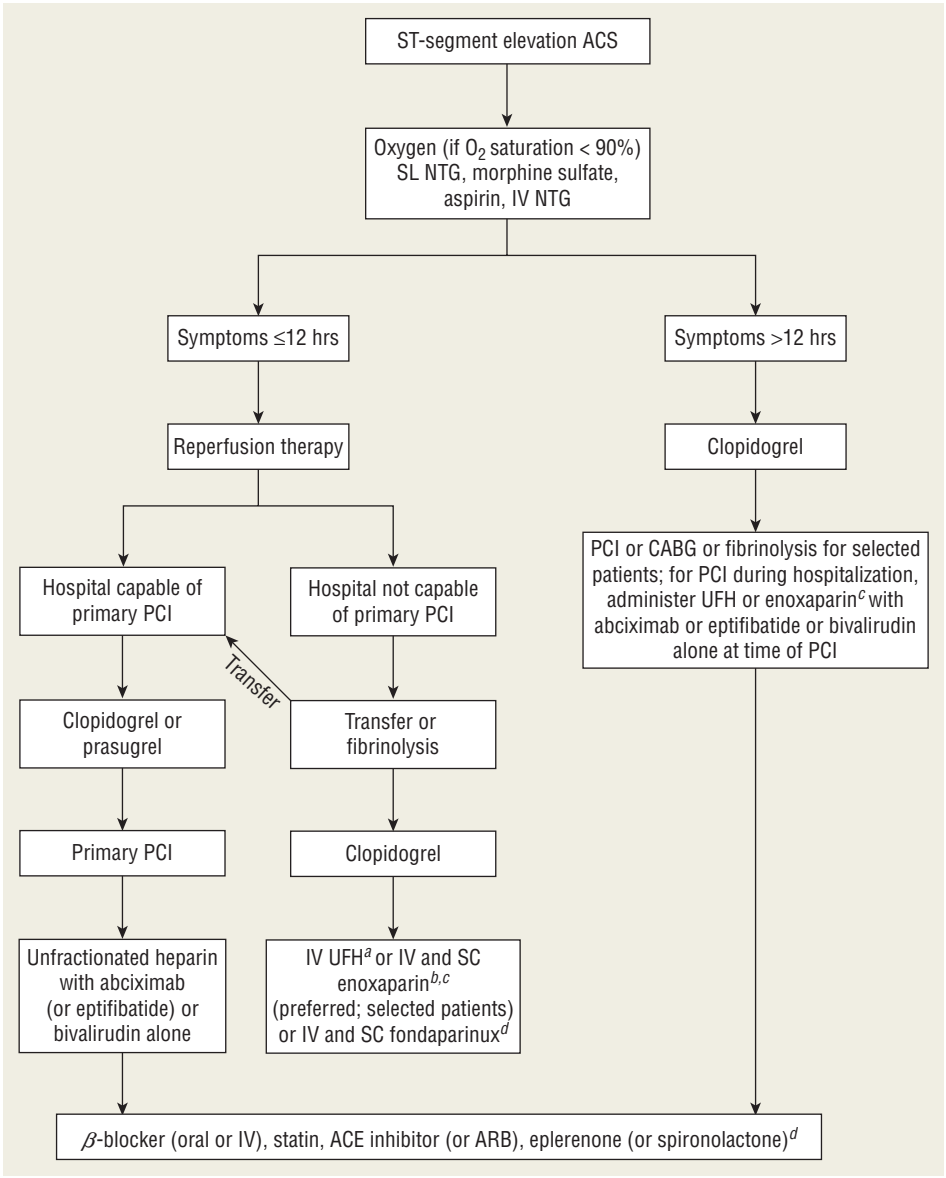

FIGURE 24-3. Initial pharmacotherapy for ST-segment elevation myocardial infarction. (ACS, acute coronary syndromes; CABG, coronary artery bypass graft surgery; IV, intravenous; NTG, nitroglycerin; PCI, percutaneous coronary intervention; SL, sublingual; UFH, unfractionated heparin.) [a]For at least 48 hours. [b]See Table 24–4 for dosing and specific types of patients who should not receive enoxaparin. [c]For the duration of hospitalization, up to 8 days. [d]For select patients, see Table 24–4. *(Reprinted with permission from Spinler SA. Evolution of antithrombotic therapy used in acute coronary syndromes. In: Richardson MM, Chessman KH, Chant C, Cheng JWM, Hemstreet BA, Hume AL, et al, eds. Pharmacotherapy Assessment Program, 7th ed. Cardiology. Lenexa, KS: American College of Clinical Pharmacy; 2010, 97–124.)*

grow in number with increasing patient age. While the ICH rate is approximately 1% in younger patients, it is 2% to 3% in older patients. There is no excess risk of stroke for patients younger than 55 years of age, whereas patients older than 75 years of age experience an excess of 8 strokes per 1,000 patients treated.[25] However, the ACC/AHA practice guidelines recommend the use of fibrinolytics for this age group, provided that the patient has no contraindications.[6] A 1% absolute mortality benefit is felt to be clinically significant, and the benefit in terms of lives saved per 1,000 patients treated has been reported to range from 10 to 80 for patients older than age of 75 years.[25] An AHA Scientific Statement concluded that a mortality benefit with fibrinolysis compared with no reperfusion has been demonstrated in patients up to age 85 years and includes deaths related to ICH, stroke, and shock which are all higher in the elderly compared with younger patients.[48] Careful attention to correct dosing of unfractionated heparin (UFH) and enoxaparin can reduce ICH and bleeding rates.[48] Because older patients may have cognitive impairment, careful history taking and assessment weighing the bleeding risk versus the benefit must be performed prior to administration of fibrinolysis.

According to the ACC/AHA STE ACS practice guideline, a more fibrin-specific agent, such as alteplase, reteplase, or tenecteplase, is preferred over a non-fibrin-specific agent, such as streptokinase.[6] Early administration of more fibrin-specific fibrinolytics opens a greater percentage of infarct arteries. Because an early open artery results in smaller infarcts, administration of fibrin-specific agents should result in lower mortality. This concept has been termed the *open-artery hypothesis.* In a large clinical trial, administration of alteplase reduced mortality by 1% (absolute reduction) and costs about $30,000 per year of life saved compared with streptokinase.[49] Two other trials compared alteplase with reteplase and alteplase with tenecteplase and found similar mortality between agents.[50,51] Therefore, either alteplase, reteplase, or tenecteplase is acceptable as a first-line agent. Most hospitals have at least two agents on their formulary. Most often, formulary decisions are based on frequency of use of fibrinolytics for other approved indications, such as ischemic stroke or pulmonary embolism, with alteplase having the most indications of the fibrin-specific agents. Administration considerations also guide formulary decision making and choice for patient treatment with alteplase being the most complex to administer as a weight-based bolus dose and a series of two sequential infusions over 90 minutes, whereas tenecteplase is given as a single, weight-based dose, and reteplase is given as two fixed doses administered 30 minutes apart without weight adjustment (**Table 24–4**). Therefore, both tenecteplase and reteplase are easier to administer than alteplase.

TABLE 24-4 Evidence-Based Pharmacotherapy for ST-segment Elevation and Non-ST-segment Elevation Acute Coronary Syndromes

Drug	Clinical Condition and ACC/AHA Guideline Recommendation[a]	Contraindications[b]	Dose and Duration of Therapy
Aspirin	STEMI, class I recommendation for all patients NSTE ACS, class I recommendation for all patients	Hypersensitivity, Active bleeding, Severe bleeding risk	160–325 mg orally once on hospital day 1 75–162 mg once daily orally starting hospital day 2 and continued indefinitely in patients not receiving an intracoronary stent 162–325 mg once daily orally for a minimum of 30 days in patients undergoing PCI receiving a bare metal stent, 3 months with a sirolimus-eluting stent and 6 months with a paclitaxel-eluting, followed by 75–162 mg once daily orally thereafter Continue indefinitely
Clopidogrel	NSTE ACS, class I recommendation added to aspirin STE MI, class I recommendation added to aspirin PCI in STE and NSTE ACS, class I recommendation In patients with aspirin allergy, class I recommendation	Hypersensitivity, Active bleeding, Severe bleeding risk	300 mg (class I recommendation) to 600 mg (class IIa recommendation) oral loading dose on hospital day one followed by a maintenance dose of 75 mg once daily starting on hospital day 2 in patients with NSTE ACS 300 mg oral loading dose followed by 75 mg po daily in patients receiving a fibrinolytic or that do not receive reperfusion therapy in patients with a STEMI Avoid loading dose with fibrinolytic in patients aged 75 years or more 300–600 mg (Class I) loading dose before or when PCI performed Discontinue at least 5 days before elective CABG surgery (class I recommendation) Administer indefinitely in patients with aspirin allergy (class I recommendation) Continue for at least 12 months (class I recommendation) and up to 15 months (class IIb recommendation) in patients with ACS managed with PCI/stent In patients receiving a fibrinolytic or that do not receive reperfusion therapy, administer for at least 14 days (Class I) and up to 1 year (Class IIa)
Prasugrel	PCI in STE and NSTE ACS, added to aspirin, class I recommendation	Active bleeding, Prior stroke or TIA	Initiate in patients with known coronary artery anatomy only (so as to avoid use in patients needing CABG surgery) (class I recommendation) Avoid in patients ≥ 75 years of age unless DM or history of prior MI 60 mg oral loading dose followed by 10 mg once daily for patients weighing ≥ 60 kg 60 mg oral loading dose followed by 5 mg once daily in patients weighing < 60 kg Discontinue at least 7 days prior to elective CABG surgery (class I recommendation) Continue for at least 12 months (class I recommendation) and up to 15 months (class IIb recommendation) in patients with ACS managed with PCI/stent
Unfractionated heparin	STE MI, class I recommendation in patients undergoing PCI, and for those patients treated with fibrinolytics, class IIa recommendation for patients not treated with fibrinolytic therapy. NSTE ACS, Class I recommendation in combination with antiplatelet therapy for conservative or invasive approach PCI, class I recommendation (NSTE ACS and STE MI)	Active bleeding, History of heparin-induced thrombocytopenia, Severe bleeding risk, recent stroke	For STE MI with fibrinolytics, administer 60 units/kg IV bolus (maximum 4000 units) heparin followed by a constant IV infusion at 12 units/kg/hr (maximum 1000 units/hr) For STE MI primary PCI, administer 50–70 units/kg IV bolus if a GPIIb/IIIa inhibitor planned; 70–100 units/kg IV bolus if no GPIIb/IIIa inhibitor planned and supplement with IV bolus doses to maintain target ACT For NSTE ACS, administer 60 Units/kg IV bolus (maximum 4000 Units) followed by a constant IV infusion at 12 Units/kg/hr (maximum 1000 Units/hr) Titrated to maintain an aPTT of 1.5 to 2.0 times control (approximately 50 to 70 sec) for STE MI with fibrinolytics and for NSTE ACS Titrated to ACT of 250 to 350 sec for primary PCI without a GP IIb/IIIa inhibitor and 200 to 250 sec in patients given a concomitant GP IIb/IIIa inhibitor The first aPTT should be measured at 4 to 6 hours for NSTE ACS and STE ACS in patients *not* treated with fibrinolytics or undergoing primary PCI The first aPTT should be measured at 3 hours in patients with STE ACS who are treated with fibrinolytics Continue for 48 hrs or until the end of PCI
Enoxaparin	STE MI class I recommendation in patients receiving fibrinolytics and class IIa for patients not undergoing reperfusion therapy NSTE ACS, class I recommendation in combination with aspirin for conservative or invasive approach For PCI, class IIa recommendation as an alternative to UFH in patients with NSTE ACS For primary PCI in STE MI, class IIb recommendation as an alternative to UFH	Active bleeding, History of heparin-induced thrombocytopenia Severe bleeding risk, Recent stroke, Avoid enoxaparin if CrCl < 15 mL/min, Avoid if CABG surgery	Enoxaparin 1 mg/kg SC every 12 hrs for patients with NSTE ACS (CrCl ≥ 30 mL/min) Enoxaparin 1 mg/kg SC every 24 hrs (CrCl 15–29 mL/min) for NSTE or STE MI For all patients undergoing PCI following initiation of SC enoxaparin for NSTE ACS, a supplemental 0.3 mg/kg IV dose of enoxaparin should be administered at the time of PCI if the last dose of SC enoxaparin was given 8–12 hrs prior to PCI For patients with STE MI receiving fibrinolytics: Age <75 yrs: administer enoxaparin 30 mg IV bolus followed immediately by 1 mg/kg SC every 12 hours (first two doses administer maximum of 100 mg for patients for weighing more than 100 kg) For patients with STE MI ≥ 75 yrs old: administer enoxaparin 0.75 mg/kg SC every 12 hours (first two doses administer maximum of 75 mg for patients weighing more than 75 kg) Continue throughout hospitalization or up to 8 days for STE MI Continue for 24–48 hours for NSTE ACS or until the end of PCI for NSTE MI
Bivalirudin	NSTE ACS class I recommendation for invasive strategy	Active bleeding, Severe bleeding risk	For NSTE ACS, administer 0.1 mg/kg IV bolus followed by 0.25 mg/kg/hr infusion For PCI in NSTE ACS, administer a second bolus of 0.5 mg/kg IV and increase infusion rate to 1.75 mg/kg/hr For PCI in STEMI administer 0.75 mg/kg IV bolus followed by 1.75 mg/kg/hr infusion If prior UHF given, discontinue UHF and wait 30 mins before initiating bivalirudin Dosage adjustment for renal failure: none required in the HORIZONS-AMI trial Discontinue at end of PCI or continue at 0.25 mg/kg/hr if prolonged anticoagulation necessary

TABLE 24-4 Evidence-Based Pharmacotherapy for ST-segment Elevation and Non-ST-segment Elevation Acute Coronary Syndromes (continued)

Drug	Clinical Condition and ACC/AHA Guideline Recommendation[a]	Contraindications[b]	Dose and Duration of Therapy
Fondaparinux	STE MI class I recommendation receiving fibrinolytics and IIa for patients not undergoing reperfusion therapy NSTE ACS class I recommendation for invasive or conservative approach	Active bleeding, Severe bleeding risk SCr ≥ 3.0 mg/dL or Clcr < 30 mL/min	For STE MI, 2.5 mg IV bolus followed by 2.5 mg SC once daily starting on hospital day 2 For NSTE ACS, 2.5 mg SC once daily For PCI, give 50 to 60 units/kg IV bolus of UFH (regimen not rigorously studied) Continue until hospital discharge or up to 8 days
Fibrinolytic therapy	STE MI, class I recommendation for patients presenting within 12 hrs following the onset of symptoms, class IIa in patients presenting between 12 and 24 hrs, following the onset of symptoms with continuing signs of ischemia NSTE ACS, class III recommendation	Any prior intracranial hemorrhage Known structural cerebrovascular lesions, such as an arterial venous malformation Known intracranial malignant neoplasm Ischemic stroke within 3 months Active bleeding (excluding menses), Significant closed head or facial trauma within 3 months	Streptokinase: 1.5 MU IV over 60 min Alteplase: 15 mg IV bolus followed by 0.75 mg/kg IV over 30 min (max 50 mg) followed by 0.5 mg/kg (max 35 mg) over 60 min (maximum dose = 100 mg) Reteplase: 10 units IV x 2, 30 min apart Tenecteplase: <60 kg (<132 lbs) = 30 mg IV bolus 60–69.9 kg (132–153 lbs) = 35 mg IV bolus 70–79.9 kg (154–176 lbs) = 40 mg IV bolus
Glycoprotein IIb/IIIa receptor inhibitors	NSTE ACS, class IIa recommendation for either tirofiban or eptifibatide for patients with either continuing ischemia, elevated troponin or other high-risk features, class I recommendation for patients undergoing PCI, class IIb recommendation for patients without high-risk features who are not undergoing PCI STE MI, class IIa for abciximab for primary PCI and class IIb for either tirofiban or eptifibatide for primary PCI	Active bleeding Thrombocytopenia Prior stroke Renal dialysis (eptifibatide)	

Drug	Dose for STE MI PCI and NSTE ACS	Dose for NSTE ACS without PCI	Dose adjustment for renal insufficiency
Abciximab	0.25 mg/kg IV bolus followed by 0.125 mcg/kg/min (maximum 10 mcg/min) for 12 hrs	Not recommended	None
Eptifibatide	180 μ/kg IV bolus X 2, 10 min apart with an infusion of 2 mcg/kg/min for 18–24 hrs after PCI	180 μ/kg IV bolus followed by an infusion of 2 mcg/kg/min for 12–72 hrs	Reduce maintenance infusion to 1 mcg/kg/min for patients with CrCl <50 mL/min; not studied in patients with serum creatinine >4.0 mg/dL; Patients weighing 121 kg (266 lbs) or more should receive a maximum infusion rate of 22.6 mg per bolus and a maximum infusion rate of 15 mg/hour
Tirofiban	25 μ/kg IV bolus Followed by an Infusion of 0.15 mcg/kg/minute for up to 18 hours	0.4 mg/kg IV bolus administered over 30 min followed by an infusion of 0.1 mcg/kg/min for 18 to 72 hours	Reduce maintenance infusion to 0.05 mcg/kg/min for patients with CrCl < 30 mL/min

(continued)

TABLE 24-4 Evidence-Based Pharmacotherapy for ST-segment Elevation and Non-ST-segment Elevation Acute Coronary Syndromes (continued)

Drug	Clinical Condition and ACC/AHA Guideline Recommendation[a]	Contraindications[b]	Dose and Duration of Therapy
Nitroglycerin	STE MI and NSTE ACS, class I indication in patients with ongoing ischemic discomfort, control of hypertension or management of pulmonary congestion	Hypotension Sildenafil or vardenafil within 24 hrs or tadalafil within 48 hours	0.4 mg SL, repeated every 5 minutes x 3 doses 5 to 10 mcg/min IV infusion titrated up to 75 to 100 mcg/min until relief of symptoms or limiting side-effects (headache) with a systolic blood pressure < 90 mm Hg or more than 30 percent below starting mean arterial pressure levels if significant hypertension is present Topical patches or oral nitrates are acceptable alternatives for patients without ongoing or refractory symptoms. Continue IV infusion for 24 to 48 hours
β-blockers[c]	STE MI and NSTE ACS, class I recommendation for oral beta-blockers in all patients without contraindications in the first 24 hrs, class IIa for IV beta-blockers in hypertensive patients	PR ECG segment >0.24 sec, 2nd degree or 3rd degree atrioventricular heart block Heart rate < 60 beats per min Systolic blood pressure < 90 mm Hg Shock Left ventricular failure with congestive heart failure Severe reactive airway disease	Target resting heart rate of 50–60 beats/min Metoprolol 5 mg slow IV push (over 1 to 2 min), repeated every 5 min for a total of 15 mg followed in 1 to 2 hours by 25 to 50 mg by mouth every 6 hours; if a very conservative regimen is desired, initial doses can be reduced to 1 to 2 mg Propranolol 0.5 to 1 mg IV dose followed in 1–2 hours by 40–80 mg by mouth every 6 to 8 hours Atenolol 5 mg IV dose followed in 5 min by a second 5 mg IV dose for a total of 10 mg, followed in 1 to 2 hours by 50 to 100 mg by mouth once daily Alternatively, initial intravenous therapy can be omitted Continue oral β-blocker indefinitely
Calcium channel blockers	STE MI class IIa recommendation and NSTE ACS class I recommendation for patients with ongoing ischemia who are already taking adequate doses of nitrates and β-blockers or in patients with contraindications to or intolerance to β-blockers (diltiazem or verapamil preferred during initial presentation) NSTE ACS, class IIb recommendation for diltiazem for patients with AMI	Pulmonary edema Evidence of left ventricular dysfunction Systolic blood pressure < 100 mm Hg PR ECG segment >0.24 sec 2nd or 3rd degree atrioventricular heart block for verapamil and diltiazem, pulse rate < 60 beats per min for diltiazem or verapamil	Diltiazem 120–360 mg sustained release orally once daily Verapamil 180–480 mg sustained release orally once daily Nifedipine 30–90 mg sustained release orally once daily Amlodipine 5–10 mg orally once daily Continue indefinitely if contraindication to oral β-blocker persists
ACE inhibitors	NSTE ACS and STE MI, class I recommendation for patients with heart failure, left ventricular dysfunction and EF ≤ 40%, type 2 diabetes mellitus or chronic kidney disease in the absence of contraindications Consider in all patients with CAD (class I recommendation, class IIa in low risk patients) Indicated indefinitely for all patients with EF <40% (class I recommendation)	Systolic blood pressure < 100 mm Hg History of intolerance to an ACE inhibitor Bilateral renal artery stenosis Serum potassium > 5.5 mEq/L (> 5.5 mmol/L) Acute renal failure Pregnancy	**Drug** / **Initial dose (mg)** / **Target dose (mg)** Captopril / 6.25–12.5 / 50 twice daily orally to 50 three times daily Enalapril / 2.5–5.0 / 10 twice daily orally Lisinopril / 2.5–5.0 / 10–20 once daily orally Ramipril / 1.25–2.5 / 5 twice daily or 10 mg once daily orally Trandolapril / 1.0 / 4 mg once daily orally
Angiotensin receptor blockers	NSTE MI and STE MI, class I recommendation in patients with clinical signs of heart failure or left ventricular EF < 40% and intolerant of an ACE inhibitor, class IIa recommendation in patients with clinical signs of heart failure or EF < 40% and no documentation of ACE inhibitor intolerance, class I in other ACE inhibitor intolerant patients with hypertension	Systolic blood pressure < 100 mm Hg Bilateral renal artery stenosis Serum potassium > 5.5 mEq/L Acute renal failure Pregnancy	**Drug** / **Initial dose (mg)** / **Target dose (mg)** Candesartan / 4–8 mg / 32 mg once daily orally Valsartan / 40 mg / 160 mg twice daily orally Continue indefinitely

(continued)

TABLE 24-4 Evidence-Based Pharmacotherapy for ST-segment Elevation and Non-ST-segment Elevation Acute Coronary Syndromes (continued)

Drug	Clinical Condition and ACC/AHA Guideline Recommendation[a]	Contraindications[b]	Dose and Duration of Therapy
Aldosterone antagonists	NSTE MI and STE MI class I recommendation with ejection fraction ≤40% and either DM or heart failure symptoms who are already receiving an ACE inhibitor	Hypotension Hyperkalemia, serum potassium >5.0 mEq/L SCr >2.5 mg/dL and/or CrCl <30 mL/min	**Drug** / **Initial dose (mg)** / **Maximum dose (mg)** Eplerenone / 25 mg / 50 mg once daily orally Spironolactone / 12.5 mg / 25–50 mg once daily orally Continue indefinitely
Morphine sulfate	STE and NSTE ACS, class I recommendation for patients whose symptoms are not relieved after three serial SL nitroglycerin tablets or whose symptoms recur with adequate anti- ischemic therapy	Hypotension Respiratory depression Confusion Obtundation	2 to 4 mg IV bolus dose May be repeated every 5 to 15 minutes as needed to relieve symptoms and maintain patient comfort

[a]Class I recommendations are conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective. Class II recommendations are those conditions for which there is conflicting evidence and/or divergence of opinion about the usefulness/efficacy of a procedure or treatment. For Class IIa recommendations, the weight of the evidence/opinion is in favor of usefulness/efficacy. Class IIb recommendations are those for which usefulness/efficacy is less well established by evidence/opinion. Class III recommendations are those where the procedure or treatment is not useful and may be harmful.

[b]Allergy or prior intolerance contraindication for all categories of drugs listed in this chart.

[c]Choice of the specific agent is not as important as ensuring that appropriate candidates receive this therapy. If there are concerns about patient intolerance due to existing pulmonary disease, especially asthma, selection should favor a short-acting agent, such as metoprolol or the ultra short-acting agent, esmolol. Mild wheezing or a history of chronic obstructive pulmonary disease should prompt a trial of a short-acting agent at a reduced dose (e.g., 2.5 mg intravenous metoprolol, 12.5 mg oral metoprolol, or 25 mcg/kg/min esmolol as initial doses) rather than complete avoidance of beta-blocker therapy.

ACC = American College of Cardiology; ACE = angiotensin converting enzyme inhibitor; AHA = American Heart Association; ACS = acute coronary syndrome; ACT = activated clotting time; ACUITY = Acute Catheterization and Urgent Intervention Triage Strategy; CABG = coronary artery bypass graft; CAD = coronary artery disease; CrCl = creatinine clearance; DM = diabetes mellitus; ECG = electrocardiogram; IV = intravenous, MI = myocardial infarction; NSTE = non-ST-segment elevation; OASIS = Organization to Assess Strategies in Acute Ischemic Syndromes; PCI = percutaneous coronary intervention; SC = subcutaneous, SCr = serum creatinine; SL = sublingual; STE = ST-segment elevation; TIA = transient ischemic attack

Pharmacotherapy Assessment Program, 7th ed. Cardiology. Lenexa, KS: American College of Clinical Pharmacy; 2010, 97–124.

ICH and major bleeding are the most serious side effects of fibrinolytic agents. The risk of ICH is higher with fibrin-specific agents than with streptokinase. Models are available for use in clinical practice to predict an individual patient's risk of ICH following administration of a fibrinolytic.[6] The risk of systemic bleeding other than ICH is higher with streptokinase than with other, more fibrin-specific agents.[49]

The percentage of eligible patients who receive reperfusion therapy is another quality performance measure of care for patients with STE MI.[23] (see Table 24–3). The "door-to-needle time," the time from hospital arrival to start of fibrinolytic therapy, is also a quality performance measure.[23] (Table 24–3) While the ACC/AHA guidelines recommend a door-to-needle time of less than 30 minutes, the median administration time in the United States in 2006 was 29 minutes with only 50% of patients meeting the quality performance measure target of <30 minutes.[10] Therefore, healthcare professionals can work to shorten fibrinolytic administration times.

Aspirin

Based on several randomized trials, aspirin is the preferred antiplatelet agent in the treatment of all ACSs.[2–6] Early aspirin administration to all patients without contraindications within the first 24 hours of hospital admission is a quality care indicator[23] (Table 24–3). The antiplatelet effects of aspirin are mediated by inhibiting the synthesis of TXA_2 through an irreversible inhibition of platelet cyclooxygenase-1.[52] Following the administration of a non-enteric-coated formulation, aspirin rapidly (<10 minutes) inhibits TXA_2 production in the platelets. Aspirin also has antiinflammatory actions, which decrease C-reactive protein and also may contribute to its effectiveness in ACS.[52] For patients undergoing PCI, aspirin prevents acute thrombotic occlusion during the procedure and likely stent thrombosis following PCI.

The Second International Study of Infarct Survival (ISIS-2), which studied the impact of streptokinase and aspirin (162.5 mg/day) either alone or in combination, is a landmark clinical trial that convincingly demonstrated the value of aspirin for patients with STE ACS.[53] In this trial (n = 17,187), patients receiving aspirin demonstrated a lower risk of 35-day vascular mortality compared with placebo (9.4% vs 11.8%; P<0.0001). The use of aspirin was not associated with any increase in major bleeding, although the incidence of minor bleeding was increased. Furthermore, the combination of aspirin plus streptokinase reduced mortality compared with placebo, as well as compared with either agent alone, thereby highlighting the additive effects of combination antithrombotic therapy.

For patients experiencing an ACS, an initial dose equal to greater than 160 mg nonenteric aspirin is necessary to achieve a rapid platelet inhibition[52,53] (Table 24–4). This first dose can be chewed in order to achieve high blood concentrations and platelet inhibition rapidly.[6] The notion of chewing aspirin came from the use of an enteric-coated formulation of aspirin in the ISIS-2 trial in order to break the enteric coating to ensure more rapid effect.[53] Current data suggest that although an initial dose 160 to 325 mg is required, long-term therapy with doses of 75 to 150 mg daily are as effective as higher doses, and therefore,[54,55] a daily maintenance dose of 75 to 162 mg is recommended in most patients to inhibit the 10% of the total platelet pool that is regenerated daily.[2–6,55] Whether these lower doses are as effective as a dose of 325 mg daily for patients undergoing intracoronary stent placement remains uncertain and current AHA/ACC guidelines recommend the use of 162 mg to 325 mg daily for one month after the placement of a bare-metal stent, 3 months after the placement of a sirolimus coated stent and 6 months after the placement of a paclitaxel coated stent, following which a daily aspirin dose of 75 mg to 162 mg should be used indefinitely.[4]

TABLE 24-5 Pharmacokinetics of Clopidogrel and Prasugrel[58,59]

	Prasugrel	Clopidogrel
Absorption and Metabolism	Prodrug Active metabolite R-138727 Metabolism to R-138727 is primarily by CYP3A4 and CYP2B6 Exposure to the active metabolite is not affected by CYP2C19 and CYP2C9 polymorphism Rapid conversion of the parent drug to active metabolite (median time to peak plasma concentration of active metabolite ≈30 minutes)	Prodrug Inactive metabolite SR266334 Active metabolite R-130946 Metabolism to R-130946 is primarily via CYP2C19, CYP3A4, CYP2B6 and CYP1A2, with lesser contribution from CYP2C9 Exposure to the active metabolite is affected by CYP2C19 genotype polymorphisms (e.g CYP2C19*2 or CYP2C19*3) Rapid conversion of the parent drug to active metabolite (mean time to peak plasma concentration of active metabolite ≈1 hour)
Food effect	Fasting administration preferred; C_{max} is reduced by 49% and t_{max} delayed 0.5–1.5 hours when administered with high-fat high-calorie meal, although AUC is unaffected	One report in healthy volunteers of bioavailability of inactive metabolite concentrations unaffected by food; one report in healthy volunteers of clopidogrel t_{max} delayed by 1.5 hrs, C_{max} increased 6-fold and bioavailability increased 9-fold
Disposition	Linear pharmacokinetics at doses up to 75 mg	Linear pharmacokinetics at doses of 50 to 150 mg
Elimination	Median elimination half-life of the active metabolite ≈7.4 hours Excretion is primarily urinary (≈70%); fecal excretion <30%	Elimination half-life of active metabolite not properly characterized, but reported to be a mean of 1.9 hours in one analysis Excretion is 50% urinary and 46% fecal
Labeled drug-drug interactions and management strategy	Enhanced bleeding with warfarin: monitor carefully for bleeding and target INR of 2.0 to 2.5 NSAIDs: avoid use if possible	Enhanced bleeding with warfarin: monitor carefully for bleeding and target INR of 2.0 to 2.5 NSAIDs: Avoid use if possible Reduced active metabolite and antiplatelet effect with inhibitors of CYP2C19: Administration of clopidogrel with agents known to inhibit CYP2C19 should be avoided. (e.g., omeprazole, esomeprazole, cimetidine, fluconazole, ketoconazole, voriconazole, etravirine, felbamate, fluoxetine, fluvoxamine)

AUC = area under the curve; CYP = cytochrome P450; INR = international normalized ratio; NSAIDs = nonsteroidal antiinflammatory drugs

Pharmacotherapy Assessment Program, 7th ed. Cardiology. Lenexa, KS: American College of Clinical Pharmacy; 2010, 97–124.

Therefore, although the risk of major bleeding, particularly gastrointestinal bleeding appears to be reduced by using lower doses of aspirin, low-dose aspirin, taken chronically, is not free of adverse effects.[55,56] Patients should be counseled on the potential risk of bleeding.

Nonselective nonsteroidal antiinflammatory agents (except aspirin) as well as cyclooxygenase-2 (COX-2) selective antiinflammatory agents should be discontinued at the time of STE MI secondary to increased risk of mortality, reinfarction, HF, and myocardial rupture.[3] Finally, although some concern has been voiced regarding the possible increased risk of hemorrhagic stroke in patients taking aspirin, this risk appears to be very small and is outweighed by the benefit in reducing the risk of ischemic stroke and other vascular events.[54] The risk of hemorrhagic stroke appears to be minimal for patients with adequate blood pressure control,[25] and there are no specific contraindications to antiplatelet therapy in a hypertensive patient presenting with ACS. Aspirin therapy should be continued indefinitely.[2–6]

Thienopyridines

Although aspirin is effective in the setting of ACS, it is a relatively weak platelet inhibitor that blocks platelet aggregation through only one pathway. The thienopyridines, ticlopidine, clopidogrel, and prasugrel, are antiplatelet agents that mediate their antiplatelet effects through a blockade of ADP $P2Y_{12}$ receptors on platelets. Because ticlopidine is associated with the occurrence of neutropenia that requires frequent monitoring of the complete blood count (CBC) during the first 3 months of use,[57] either clopidogrel or prasugrel are the preferred thienopyridines for ACS and PCI patients.[5] (Table 24–4)

Clopidogrel is currently recommended by the AHA/ACC guidelines as an alternative to aspirin for patients who have an allergy to aspirin.[2,6] For STE MI, either clopidogrel or prasugrel, in addition to aspirin 325 mg, should be administered to patients undergoing primary PCI.[5] Both clopidogrel and prasugrel are prodrugs that are converted to an active metabolite by a variety of CYP isoenzymes (Table 24–5).[12,58,59] Prasugrel is a third-generation thienopyridine that is a more potent antiplatelet agent, resulting in a higher percentage of platelet aggregation inhibition and is less dependent on CYP 2C19 to produce its active metabolite and therefore has fewer drug–drug interactions.[59,60]

For primary PCI, clopidogrel is administered as a 300 mg to 600 mg loading dose followed by 75 mg once daily, to prevent subacute stent thrombosis and long-term CV events.[5,61] Prasugrel is administered as a loading dose of 60 mg followed by a maintenance dose of 10 mg daily. A large randomized, double-blind study, Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel (TRITON)-Thrombolysis in Myocardial Infarction (TIMI) 38, compared the 15-month efficacy and safety of prasugrel versus clopidogrel added to aspirin for patients undergoing PCI in the setting of STE MI or NSTE ACS.[62] Prasugrel significantly reduced the frequency of the primary composite end point of CV death, stroke or MI by 19% (9.9% vs 12.1%), as well as MI and stent thrombosis, but increased the risk of major bleeding (not ICH), by 32% (2.4% vs 1.8%). Patients with a history of prior stroke or transient ischemic attack had an increased risk of ICH and no net clinical benefit from prasugrel and thus the product label lists prior stroke or transient ischemic attack (TIA) as a contraindication to prasugrel.[59,62] Patients over the age of 75 years and those weighing less than 60 kg are at increased risk of bleeding with prasugrel compared with clopidogrel.[59] Two subgroups of patients *do not* have an increased bleeding risk with prasugrel compared with clopidogrel and have even greater benefit, namely patients undergoing primary PCI for STE MI and those patients with a history

of diabetes mellitus.[63,64] While some have suggested that prasugrel is preferred in those two groups of patients, the most recent ACC/AHA STE MI and PCI practice guideline update does not favor one agent over another.[5,65]

Pharmacogenetic differences in thienopyridine metabolism, namely poor metabolism of CYP2C19, also can result in some patients being less responsive and thus displaying lower antiplatelet aggregation inhibition effects.[66] Lower rates of platelet aggregation inhibition [also known as (aka) responsiveness] to clopidogrel have been associated with higher rates of CV events, especially stent thrombosis and periprocedural MI in clinical trials.[67] While clopidogrel product labeling currently suggests that genetic testing and alternative therapy should be sought for patients that are CYP2C19 poor metabolizers, the cost of testing is estimated to be between $275 and $500 per patient; no prospective studies on using such a strategy to direct therapy have been published to assess the cost-effectiveness of such an approach.[58] In addition, poor responsiveness of antiplatelet effect to clopidogrel is but one predictor of increased risk of recurrent CV events following PCI. While functional platelet aggregation testing is available, there is no one gold-standard test. Prasugrel is not as dependent on *CYP2C19* genotype for its conversion to the active metabolite and has a lower frequency of poor antiplatelet responsiveness.[68] Higher maintenance doses of clopidogrel of 150 mg daily have been studied for short-term administration and appear to have a lower frequency of poor antiplatelet responsiveness, but prasugrel's antiplatelet effects at 10 mg daily are still greater than clopidogrel at 150 mg daily.[60,69] Therefore, at the time of this writing, practitioners have no clear direction on how to incorporate pharmacogenetic testing of patients taking clopidogrel into practice.

The recommended duration of thienopyridine therapy for a patient undergoing PCI for ACS, either STE MI or NSTE ACS, is at least 12 months for patients receiving either a bare-metal or a drug-eluting stent, and up to 15 months for patients receiving a drug-eluting stent for patients at low risk of bleeding (Table 24–4).[5]

While prasugrel has been studied in the setting of PCI, no studies have evaluated its use when added to both aspirin and a fibrinolytics. Therefore, clopidogrel is the preferred thienopyridine for patients receiving fibrinolysis reperfusion therapy.[3] A large trial of more than 45,000 Chinese patients with STE MI showed that early therapy with clopidogrel 75 mg once daily (started within 24 hours of hospital presentation), added to aspirin for the duration of hospitalization (average 15 days) or up to 28 days, reduced mortality and reinfarction compared with placebo for patients treated with medical therapy, including fibrinolytics, without increasing the risk of major bleeding.[70] Another smaller study showed that clopidogrel added to aspirin reduced the composite rate of 30-day death, MI, or stroke by 20% for patients ages 18 to 75 years with STE MI treated with fibrinolytics.[71] Clopidogrel or placebo was administered as an initial dose of 300 mg orally on day one followed by 75 mg daily. Angiography was encouraged as early as hospital day 2 and patients undergoing PCI at the time of angiography continued on open-label, clopidogrel, a 300 mg loading dose followed by 75 mg once daily, for the duration of the study. Patients who did not undergo revascularization received clopidogrel up to the time of discharge or hospital day 8. At the time of angiography, there were more open infarct arteries in the clopidogrel-treated patients. Based on current data, therefore, clopidogrel (either 75 mg or 300 mg on day 1 followed by 75 mg once daily) should be given for at least 14 to 28 days in addition to aspirin for patients treated by fibrinolytics and in those receiving no revascularization therapy with either PCI or CABG surgery.[3] The safety of a 300 mg loading dose has not been evaluated in patients over the age of 75 years receiving a fibrinolytic.

The most frequent side effects of clopidogrel and prasugrel are nausea, vomiting, and diarrhea, which occur in approximately 2% to 5% of patients.[58,59] Rarely, thrombotic thrombocytopenic purpura has been reported with clopidogrel and is a precaution in the prasugrel product labeling.[58,59] The most serious side effect of thienopyridines is bleeding, and patients should be counseled on self-monitoring for signs of gastrointestinal bleeding and intolerable bruising. Abrupt discontinuation of thienopyridines for patients with intracoronary stents has resulted in abrupt stent closure which carries a high mortality risk.[72] Therefore, pharmacists play an integral role in reinforcing adherence to dual antiplatelet therapy.

Glycoprotein IIb/IIIa Receptor Inhibitors

GP IIb/IIIa receptor inhibitors block the final common pathway of platelet aggregation, namely, cross-linking of platelets by fibrinogen bridges between the GP IIb and IIIa receptors on the platelet surface. If UFH is selected for primary PCI in STE MI, a GP IIb/IIIa inhibitor, most commonly eptifibatide or abciximab, should be added to UFH (in addition to clopidogrel or prasugrel and aspirin) to reduce the likelihood of reinfarction for patients who have not received fibrinolytics.[4,6,73] GP IIb/IIIa inhibitors should not be administered for medical management of the patient with STE MI who will not be undergoing PCI. Abciximab is the most common GP IIb/IIIa receptor inhibitor studied in primary PCI trials.[3,4,73] Abciximab, in combination with aspirin, a thienopyridine, and UFH (administered as an infusion for the duration of the procedure) reduced mortality and reinfarction without increasing the risk of major bleeding in a meta-analysis of primary PCI clinical trials.[73] Administration of a GP IIb/IIIa inhibitor with bivalirudin, an alternative anticoagulant to UFH for PCI, is associated with increased risk of bleeding and should be avoided if possible.[74]

Dosing and contraindications for GP IIb/IIIa inhibitors are described in Table 24–4.[12] Abciximab typically is initiated as an IV bolus followed by an IV infusion at the time of PCI, and the infusion is continued for 12 hours while eptifibatide is administered as a double IV bolus followed by an infusion and continued for 12 to 18 hours. Administration of a GP IIb/IIIa receptor inhibitor may increase the risk of bleeding, especially if it is given in the setting of recent (<4 hours) administration of fibrinolytic therapy.[73,75] An immune-mediated thrombocytopenia occurs in approximately 5% of patients with abciximab and less than 1% of patients receiving eptifibatide or tirofiban.[76]

Anticoagulants

Options for anticoagulant therapy for patients with STE ACS are outlined in Figure 24–3 and Table 24–4.[2–6,12] For patients undergoing primary PCI, either UFH or bivalirudin is preferred whereas for fibrinolysis, enoxaparin is preferred.[3,6,77–79]

Unfractionated heparin has been the traditional anticoagulant administered to patients with STE MI to prevent reocclusion of an infarct artery for more than 40 years. A meta-analysis of small randomized studies from the 1970s and 1980s suggests that UFH reduces mortality by approximately 17% compared with no anticoagulant therapy.[6] In studies of patients receiving fibrinolytics, both fondaparinux, an indirect-acting factor Xa inhibitor, and reviparin, an investigational low-molecular-weight heparin (LMWH), have shown mortality reductions compared with placebo (no anticoagulant therapy).[80,81] Other beneficial effects of anticoagulation are prevention of cardioembolic stroke, as well as venous thromboembolism in MI patients.[6] Because randomized controlled clinical trials comparing UFH with placebo are lacking, no conclusive data exist supporting a benefit of UFH over placebo

in reducing mortality or reinfarction in STE MI.[82] On the contrary, the results of a meta-analysis of more than 7,500 patients suggests that LMWHs reduce both mortality and reinfarction compared with placebo.[82]

Limitations of UFH anticoagulation include the need for intravenous infusion therapy, frequent aPTT monitoring, and the risk of heparin-induced thrombocytopenia. Bivalirudin is a direct thrombin inhibitor that has been associated with similar outcomes and reduced bleeding rates in primary PCI compared with UFH. In the Harmonizing Outcomes with Revascularization and Stents in Acute Myocardial Infarction (HORIZONS-AMI) open-label trial, patients treated with bivalirudin as a bolus and short-term infusion continued only through the PCI procedure, reduced the frequency of CV and all-cause mortality at 1 year, and lowered the risk of in-hospital major bleeding events compared with UFH.[77]

Enoxaparin, administered for a median of 7 days, has shown a reduction in the risk of death or nonfatal MI compared with UFH administered for a median of 2 days in the large, randomized Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Treatment (ExTRACT)-TIMI 25 trial.[78] (See Table 24–4 for enoxaparin dosing for STE MI.) The benefit, although modest, was already apparent after 48 hours of treatment. Enoxaparin use was associated with a small (2.1% vs 1.4%) but significant increased risk of major bleeding. Whether the observed benefits and increase in bleeding observed in this trial can be solely attributed to the pharmacokinetic and pharmacodynamic differences between UFH and enoxaparin or the longer duration of treatment in the enoxaparin group is uncertain. Although the bleeding rates were increased for patients over the age of 75 years compared with younger patients, the rates of major bleeding were similar between enoxaparin and UFH.[79] Therefore, enoxaparin can be considered a valuable anticoagulant when fibrinolysis reperfusion therapy is select for STE MI. Insufficient data are available studying IV enoxaparin in the setting of primary PCI.[83]

Fondaparinux has recently been studied in the setting of STE MI. In the Organization for the Assessment of Strategies for Ischemic Syndromes (OASIS) 6 trial, fondaparinux, administered for a median of 8 days, had similar efficacy and safety as UFH, administered for a median of 2 days, for patients receiving fibrinolytic therapy with either alteplase, reteplase, or tenecteplase[84] (see Table 24–4 for dosing). A small reduction in mortality was observed for patients treated with fondaparinux versus placebo for patients treated with streptokinase or receiving no fibrinolytic therapy. No benefit of fondaparinux was observed in the subgroup of patients undergoing PCI during hospitalization.[84] Because of the lack of benefit of fondaparinux compared with UFH as well as in the subgroup of patients undergoing PCI, coupled with the relatively long duration of administration, it is unlikely fondaparinux will be used widely in practice in the United States for STE MI.

Anticoagulant therapy should be initiated in the emergency department and continued for 48 hours or longer in select patients who will be bridged over to receive chronic warfarin anticoagulation following acute MI.[5] If a patient undergoes a PCI, UFH or bivalirudin is discontinued immediately after the procedure. The dose of the UFH infusion is adjusted frequently to a target activated partial thromboplastin time (aPTT) (see Table 24–4). When coadministered with a fibrinolytic, aPTTs above the target range are associated with an increased rate of bleeding, whereas aPTTs below the target range are associated with increased mortality and reinfarction.[85] Enoxaparin dosing is adjusted for body weight and renal function and, when administered in combination with fibrinolysis, has special dosing requirements for older patients and those weighing more than 100 kg. Fondaparinux is administered as a comparatively low, fixed dose of 2.5 mg subcutaneously daily and is contraindicated for patients with creatinine clearance less than 30 mL/min. For patients who do not undergo reperfusion therapy, it is reasonable to administer anticoagulant therapy for the duration of hospitalization, up to 8 days. Besides bleeding, the most frequent adverse effect of UFH is an immune-mediated clotting disorder, heparin-induced thrombocytopenia (see Chap. 26), which occurs in up to 5% of patients treated with UFH. Heparin-induced thrombocytopenia is less common for patients receiving LMWHs.[6]

Nitrates

Nitrates promote the release of nitric oxide from the endothelium, which results in venous and arterial vasodilation at higher doses. Venodilation lowers preload and myocardial oxygen demand. Arterial vasodilatation may lower blood pressure, thus reducing myocardial oxygen demand. Arterial vasodilatation also relieves coronary artery vasospasm, dilating coronary arteries to improve myocardial blood flow and oxygenation. One SL NTG tablet (0.4 mg) should be administered every 5 minutes for up to 3 doses to relieve myocardial ischemia. If patients have previously been prescribed SL NTG and ischemic chest discomfort persists for more than 5 minutes after the first dose, the patient should be instructed to contact emergency medical services before self-administering subsequent doses in order to activate emergency care sooner. IV NTG is indicated for patients with an ACS who do not have a contraindication and who have persistent ischemic symptoms, HF, or uncontrolled high blood pressure in the absence of contraindications (see Table 24–4). IV NTG should be continued for approximately 24 hours after ischemia is relieved.[6] Importantly, other life-saving therapies, such as ACE inhibitors or β-blockers, should not be withheld to use nitrates because the mortality benefit of nitrates is unproven. Nitrates play a limited role in the treatment of ACS patients because two large, randomized clinical trials failed to show a mortality benefit for IV followed by oral nitrate therapy in acute MI.[86,87] The most significant adverse effects of nitrates are tachycardia, flushing, headache, and hypotension. Nitrate administration is contraindicated for patients who have received oral phosphodiesterase-5 inhibitors, such as sildenafil and vardenafil within the past 24 hours and tadalafil within the past 48 hours. Because PCI or CABG restores coronary artery blood flow, NTG is typically not continued following revascularization.

β-Blockers

A β-blocker should be administered early in the care of patients with STE ACS and continued indefinitely. In ACS, the benefit of β-blockers results mainly from the competitive blockade of β_1-adrenergic receptors located on the myocardium. β_1-Blockade produces a reduction in heart rate, myocardial contractility, and blood pressure, decreasing myocardial oxygen demand. In addition, the reduction in heart rate increases diastolic time, thus improving ventricular filling and coronary artery perfusion.[88] As a result of these effects, β-blockers reduce the risk for recurrent ischemic, infarct size, risk of reinfarction, and occurrence of ventricular arrhythmias in the hours and days following MI.[88]

Landmark clinical trials have established the role of early β-blocker therapy in reducing MI mortality. Most of these trials were performed in the 1970s and 1980s before routine use of early reperfusion therapy.[89–92] However, data regarding the acute benefit of β-blockers in MI in the reperfusion era are derived mainly from a more recent large clinical trial that suggests that although initiating IV followed by oral β-blockers early in the course of STE MI was associated with a lower risk of reinfarction or ventricular fibrillation, there may be an early risk of cardiogenic shock, especially for patients presenting with pulmonary congestion or systolic blood pressure >120 mm Hg.[93] Therefore, initiation of β-blockers, particularly when administered intravenously, should be limited

to patients who are hemodynamically stable and who do not demonstrate any signs or symptoms of acute HF.[3] Careful assessment for signs of hypotension and HF should be performed following β-blocker initiation and prior to any dose titration. Patients already taking β-blockers can continue taking them. STEMI 2007 The Joint Commission has retired the "Beta Blocker at Hospital Arrival" Core Measure and is no longer requiring hospital reporting of this measure.

The most serious side effects of β-blocker administration early in ACS are hypotension, acute HF, bradycardia, and heart block. While initial acute administration of β-blockers is not appropriate for patients who present with acute HF, initiation of β-blockers may be attempted before hospital discharge for most patients following treatment of acute HF. β-Blockers are continued indefinitely.[6]

Calcium Channel Blockers

Administration of calcium channel blockers in the setting of STE MI is reserved for patients who have contraindications to β-blockers and is used for relief of ischemic symptoms.[6] Patients prescribed calcium channel blockers for treatment of hypertension who are not receiving β-blockers and who do not have a contraindication to β-blockers should have the calcium channel blocker discontinued and a β-blocker initiated. Calcium channel blockers inhibit calcium influx into myocardial and vascular smooth muscle cells, causing vasodilation. Although all calcium channel blockers produce coronary vasodilatation and decrease blood pressure, other effects are more heterogeneous between agents. Dihydropyridine calcium channel blockers (e.g., amlodipine, felodipine, and nifedipine) primarily produce their antiischemic effects through peripheral vasodilatation with no clinical effects on atrioventricular (AV) node conduction and heart rate. Diltiazem and verapamil, on the other hand, have additional antiischemic effects by reducing contractility and AV nodal conduction and slowing heart rate.[94]

Current data suggest little benefit on clinical outcomes beyond symptom relief for calcium channel blockers in the setting of ACS.[94,95] Moreover, the use of first-generation short-acting dihydropyridines, such as nifedipine, should be avoided because they appear to worsen outcomes through their negative inotropic effects, induction of reflex sympathetic activation, tachycardia, and increased myocardial ischemia.[94] Therefore, the role of verapamil or diltiazem appears to be limited to relief of ischemia-related symptoms or control of heart rate in patients with supraventricular arrhythmias for whom β-blockers are contraindicated or ineffective.[6]

Adverse effects and contraindications of calcium channel blockers are described in Table 24–4. Verapamil, diltiazem, and first-generation dihydropyridines also should be avoided for patients with acute HF or LV systoilic dysfunction because they can worsen HF and potentially increase mortality secondary to their negative inotropic effects. For patients with HF requiring treatment with a calcium channel blocker, amlodipine is the preferred agent.[96,97]

Two groups of patients may benefit from calcium channel blockers as opposed to β-blockers as initial therapy. Cocaine-induced ACS and variant (or Prinzmetal) angina are two conditions in which coronary vasospasm plays an important role.[6,98] Calcium channel blockers and/or NTG generally are considered the agents of choice in these patients because they can reverse the coronary spasm by inducing smooth muscle relaxation in the coronary arteries. In contrast, β-blockers generally should be avoided in these patients unless there is uncontrolled sinus tachycardia (>100 beats per minute) or severe uncontrolled hypertension following cocaine use because β-blockers actually may worsen vasospasm through an unopposed β_2-blocking effect on the smooth muscle cells.[98]

EARLY PHARMACOTHERAPY FOR NON-ST-SEGMENT ELEVATION ACS

In general, early pharmacotherapy for NSTE ACS (see Fig. 24–4) [12] is similar to that for STE. 8 According to the 2007 ACC/AHA NSTE ACS practice guidelines, early pharmacotherapy includes intranasal oxygen (if oxygen saturation is low), aspirin, SL NTG, and an anticoagulant, either UFH, enoxaparin, fondaparinux, or bivalirudin. High-risk patients should proceed to early coronary angiography and may additionally receive a glycoprotein IIb/IIIa receptor inhibitor. Clopidogrel or prasugrel [agent and timing dependent on selection of an interventional (PCI) or medical management strategy] should be administered to all patients. Intravenous β-blockers and nitroglycerin should be given to select patients. Morphine is also administered to patients with refractory angina, as described previously. Intravenous NTG should be administered in select patients. Aspirin, SL NTG, and anticoagulation should be initiated early, while the patient is still in the emergency department. Fibrinolytic therapy is never administered. Dosing and contraindications for SL and IV NTG, aspirin, β-blockers, thienopyridines, and anticoagulants are listed in Table 24–4.[2–6,12]

Fibrinolytic Therapy

Fibrinolytic therapy is not indicated in any patient with NSTE ACS, even those who have positive biochemical markers (e.g., troponin) that indicate infarction. Because the risk of death from MI is lower for patients with NSTE ACS, whereas the risk for life-threatening adverse effects, such as ICH, with fibrinolytics is similar between patients with STE and NSTE ACS, the risks of fibrinolytic therapy outweigh the benefit for NSTE ACS patients. In fact, increased mortality has been reported with fibrinolytics compared with controls in clinical trials where fibrinolytics have been administered to patients with NSTE ACS (patients with normal or ST-segment-depression ECGs).[25]

Aspirin

Aspirin reduces the risk of death or developing MI by about 50% (compared with no antiplatelet therapy) for patients with non-STE ACS.[55] Therefore, aspirin remains the cornerstone of early treatment for all ACSs. Dosing of aspirin for NSTE ACS is the same as that for STE ACS (see Table 24–4).[2] Aspirin is continued indefinitely.

Thienopyridines

For patients with NSTE ACS, either clopidogrel or prasugrel is indicated for patients managed invasively with early coronary angiography and revascularization, while clopidogrel is indicated in those early conservatively managed patients. Clopidogrel is recommended for low- to moderate-risk patients, in addition to aspirin, who are managed with early conservative therapy, while clopidogrel or prasugrel may be selected in addition to aspirin and anticoagulation, in high-risk patients.[2,5] Clopidogrel is initiated as either a 300 mg or 600 mg loading dose followed by 75 mg daily, while prasugrel is initiated as a 60 mg loading dose followed by 10 mg daily.[5] Efficacy and safety of dual oral antiplatelet therapy were demonstrated in the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial.[99,100] In CURE, 12,562 patients with UA or an NSTEMI and new ECG changes consistent with ischemia or positive cardiac markers were randomized to a loading dose of 300 mg clopidogrel followed by a daily dose of 75 mg or placebo in addition to aspirin for a mean duration of 9 months and up to 12 months.[99] Clopidogrel reduced the combined risk of death from cardiovascular causes, nonfatal MI, or stroke from 11.4% to 9.4% compared with placebo, mainly through a reduction in the risk of MI. Cardiovascular mortality was similar between groups. In the subgroup of patients undergoing PCI, clopidogrel reduced the rate

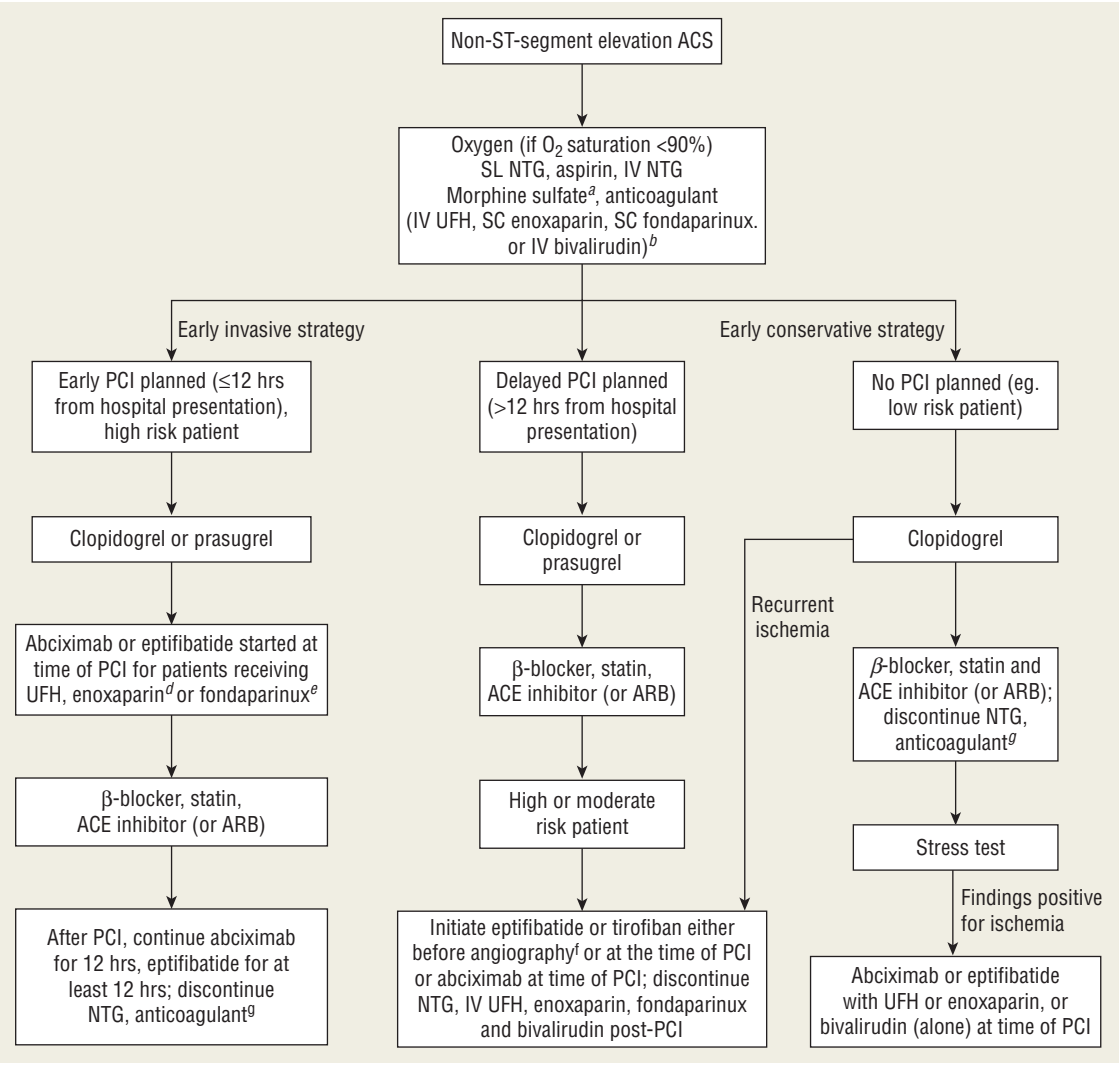

FIGURE 24-4. Initial pharmacotherapy for non-ST-segment elevation acute coronary syndrome. (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; ACS, acute coronary syndrome; CABG, coronary artery bypass graft surgery; IV, intravenous; NTG, nitroglycerin; PCI, percutaneous coronary intervention; SC, subcutaneous; SL, sublingual; UFH, unfractionated heparin.) [a]For select patients, see Table 24–4. [b]Enoxaparin, UFH, fondaparinux plus UFH, or bivalirudin for early invasive strategy; enoxaparin or fondaparinux if no angiography/PCI planned; fondaparinux or bivalirudin preferred if high risk of bleeding; UFH preferred if patients going for CABG. [c]For patients unlikely to undergo CABG. [d]May require an IV supplemental dose of enoxaparin, see Table 24–4. [e]May require an IV supplemental dose of UFH, see Table 24–4. [f]For signs and symptoms of recurrent ischemia. [g]SC enoxaparin or UFH can be continued at a lower dose for venous thromboembolism prophylaxis. *(Reprinted with permission from Spinler SA. Evolution of antithrombotic therapy used in acute coronary syndromes. In: Richardson MM, Chessman KH, Chant C, Cheng JWM, Hemstreet BA, Hume AL, et al, eds. Pharmacotherapy Assessment Program, 7th ed. Cardiology. Lenexa, KS: American College of Clinical Pharmacy; 2010, 97–124.)*

of CV death or MI by 28% compared with placebo.[100] Results from a second trial in PCI patients, the Clopidogrel for the Reduction of Events During Observation (CREDO) trial, in which patients treated with long-term clopidogrel (1 year), demonstrated a lower risk of death, MI, or stroke compared with patients receiving only 28 days of clopidogrel added to aspirin compared with placebo (8.5% vs 11.5%; $P = .02$).[101] However, the interpretation of this study is limited in that the control group did not receive a loading dose of clopidogrel on the first day.

Prasugrel, a thienopyridine with greater antiplatelet effects than clopidogrel, reduced the risk of CV death, MI, and stroke in the TRITON-TIMI 38 trial as described in the section Early Pharmacotherapy for STE MI.[62] In TRITON-TIMI 38, 74% of patients enrolled had NSTE ACS. As described previously, prasugrel-treated patients had a higher rate of major bleeding. As part of the study design, the thienopyridine was initiated following coronary angiography at the time of PCI rather than initiated in the emergency department. Therefore, the 2009 ACC/AHA STEMI and PCI guideline update provides an option for these agents to be initiated at the time of angiography/PCI in high-risk patients and also reserve prasugrel for patients in the early intervention strategy.[5] Clopidogrel remains the thienopyridine of choice for patients not undergoing revascularization (also termed *medical therapy alone*).[2] In CURE, the subgroup of patients not undergoing revascularization had a significant 20% reduction in CV events.[99]

Based upon the duration of thienopyridine administration in CURE and TRITON-TIMI 38, current guidelines for patients with NSTE ACS recommend that clopidogrel or prasugrel be administered for at least 12 months for patients undergoing PCI with placement of either a bare-metal or drug-eluting stent and up to 15 months for patients with a drug-eluting stent, where the risk of thrombotic occlusion may be greater.[5] For medical therapy of NSTE ACS, clopidogrel should be administered for up to 12 months for patients not at high risk of bleeding[2] (see **Table 24–4**).

The major concern when combining two antiplatelet agents is the increased risk of bleeding. In CURE, the risk of major bleeding was increased for patients receiving clopidogrel plus aspirin compared with aspirin alone (3.7% vs 2.7%; $P = 0.001$).[99] A post hoc analysis of CURE revealed that the rate of major bleeding depends on the dose of aspirin and showed that doses equal to or less than 100 mg daily reduced the risk of bleeding with similar efficacy when compared with higher doses.[102] The recommendation to use a lower dose of aspirin with clopidogrel is also supported by the results of a recent systematic review of clinical trials that found no benefit to aspirin as a sole antiplatelet agent for chronic treatment in doses greater than 75 to 81 mg.[54] However, a dose of 162 to 325 mg of aspirin is recommended to be administered with clopidogrel to patients with recent intracoronary stent placement, as described in the section on STE MI Pharmacotherapy, to prevent stent thrombosis[5] (see Table 24–4).

For patients undergoing CABG, major bleeding was increased in patients having the procedure within 5 days of clopidogrel discontinuation (9.6% vs 6.3%; $P = 0.06$) but not in patients for which clopidogrel was discontinued more than 5 days before the procedure.[99] Aspirin was continued up to and after CABG. Therefore, for patients scheduled for CABG, clopidogrel should be withheld at least 5 days and preferably 7 days before the procedure.[2,3,5]

In TRITON-TIMI 38, the frequency of major bleeding was higher in prasugrel- versus clopidogrel-treated patients (2.4% vs 1.8%, hazard ratio 1.32; 95% CI, 1.03–1.68; $P = 0.03$).[62] Prasugrel is contraindicated for patients with a prior history of stroke or TIA as the ICH rate was numerically higher without a net clinical benefit.[59,62] Patients older than 75 years of age have a greater risk of bleeding with prasugrel compared with clopidogrel as do patients weighing less than 60 kg.[59] For patients weighing less than 60 kg, a lower maintenance dose of 5 mg is recommended.[59] No outcome information from clinical trials evaluating safety of this dose has been reported. Hence, clopidogrel may be preferred for patients older than 75 years of age and in those weighing less than 60 kg.

Glycoprotein IIb/IIIa Receptor Inhibitors

Administration of abciximab or eptifibatide (alternatively tirofiban) with aspirin and UFH or enoxaparin is recommended for high-risk NSTE ACS patients undergoing PCI.[2,3] Administration of tirofiban or eptifibatide is also indicated for patients with continued or recurrent ischemia despite treatment with aspirin, clopidogrel, and an anticoagulant.[2] The pharmacologic similarities and differences between GP IIb/IIIa receptor inhibitors are reviewed in Chap. 23. As discussed in Chap. 23, the benefits of GP IIb/IIIa receptor inhibitors in PCI is well established, and they are considered a first-line agent to reduce the risk of reinfarction and the need for repeat PCI when added to aspirin and either UFH or enoxaparin.[2,3] A limitation of such studies is that they were conducted at a time when thienopyridines were not routinely administered prior to angiography and the practice was not standardized during the GP IIb/IIIa receptor inhibitor trials, and so such use was inconsistent between studies. A meta-analysis of five contemporary trials where clopidogrel pretreatment was required demonstrated no additional benefit for GP IIb/IIIa inhibitors over placebo, in terms of reduction in mortality, MI, or need for coronary artery revascularization with PCI, for either elective PCI for patients with stable angina or PCI in the setting of ACS.[103] In another 2008 meta-analysis of all studies published at the time, the beneficial reduction in the frequency of death or MI was greater for the patients with highest-risk such as those with positive troponins or those with a history of diabetes mellitus.[104] A third meta-analysis estimated that 30 adverse outcomes (either death or MI) are prevented for every 1,000 patients treated with a GP IIb/IIIa inhibitor before PCI, whereas only 4 events are prevented for medical management of patients with NSTE ACS using GP IIb/IIIa inhibitors without PCI.[104] Major and minor bleeding rates were increased in all of these reports.[103–105] A study of routine use of these agents in high-risk patients prior to angiography, termed *upstream* administration, compared with initiation at the time of coronary angiograph, termed *downstream administration*, showed that upstream administration does not reduce ischemic events but does increase risk of bleeding.[106] Therefore, the use of GP IIb/IIIa receptor inhibitors in NSTE ACS is restricted to high-risk patients undergoing PCI and those lower-risk patients with unremitting or recurrent ischemic symptoms after initial medical therapy who will eventually undergo coronary angiography and PCI[2,5] (Table 24–4).

Doses and contraindications to GP IIb/IIIa inhibitors are described in Table 24–4, and common adverse effects are described in the preceding section on STEMI Pharmacotherapy. Administration of an IV GP IIb/IIIa receptor inhibitor in combination with aspirin and either UFH or enoxaparin results in major bleeding rates of 0.4% to 10.6% but no increased risk of ICH in the absence of concomitant fibrinolytic treatment.[107,108] Risk factors that increase the chance of bleeding with a GP IIb/IIIa inhibitor include female gender, older age, and reduced renal function.[109] In fact, older patients, especially women, are more likely to receive an excessive dose of a GP IIb/IIIa inhibitor, which can result in bleeding.[110] Since both eptifibatide and tirofiban require dose reductions for patients with renal insufficiency (see Table 24–4), careful attention to calculating creatinine clearance and dose adjustment is required for these agents. The risk of thrombocytopenia with tirofiban and eptifibatide appears to be lower than that with abciximab. Bleeding risks appear similar among agents.

Anticoagulants

The choice of anticoagulant for a patient with NSTE ACS is guided by risk stratification, treatment strategy, and the results of recent clinical trials.[2,74] For patients undergoing an early invasive strategy with early coronary angiography and PCI, either UFH, LMWH, low-dose fondaparinux, or bivalirudin should be administered.[3] If fondaparinux is chosen for a patient who undergoes PCI, it should be administered in combination with UFH as the dose of fondaparinux studied appears too low to prevent thrombotic events during PCI. UFH is the preferred anticoagulant following angiography for patients subsequently undergoing CABG during the same hospitalization.[2] For patients receiving an early conservative strategy, either enoxaparin or fondaparinux is preferred.[2] Therapy should be continued for up to at least 48 hours for UFH, until the patient is discharged from the hospital for either enoxaparin or fondaparinux and until the end of PCI or angiography procedure (or up to 72 hours following PCI) for bivalirudin.[2] UFH is the preferred anticoagulant following angiography for patients subsequently undergoing CABG during the same hospitalization as it has a short duration of action following discontinuation when the patient is proceeding to surgery.[2] For patients presenting with NSTE ACS in whom clinicians suspect a high risk for bleeding while receiving an anticoagulant, fondaparinux is the preferred anticoagulant recommended by the ACC/AHA NSTE ACS guidelines.[2] Neither fondaparinux or bivalirudin are Food and Drug Administration (FDA) approved for NSTE ACS despite being recommended by the ACC/AHA NSTE ACS guidelines. For patients initiating warfarin therapy, UFH or LMWHs should be continued until the international normalization ratio (INR) with warfarin is in the therapeutic range.

Data supporting the addition of UFH to aspirin stem from a meta-analysis of six randomized trials demonstrating a 33% reduction in the risk of death or MI at 6 weeks with UFH plus aspirin compared with aspirin alone.[111] One trial compared the LMWH dalteparin plus aspirin with aspirin alone and found a 60% reduction in death or MI at 6 days.[112] Three clinical trials have compared

UFH with LMWHs using an early conservative strategy in NSTE ACS.[113–115] One large clinical trial of enoxaparin compared with UFH in more than 10,000 patients using an early interventional approach found similar efficacy with a higher risk of major bleeding with enoxaparin (9.1% vs 7.6%; $P = 0.008$).[116] The risk of major bleeding with UFH or LMWHs is higher in patients undergoing angiography because there is an associated risk of hematoma at the femoral access site. The risk of heparin-induced thrombocytopenia is lower in some, but not all, clinical trials with LMWHs compared with UFH.

A low-dose of fondaparinux, 2.5 mg administered once daily subcutaneously, was compared with the usual NSTE ACS dose of enoxaparin, 1 mg/kg administered every 12 hours, in OASIS-5, the largest NSTE ACS trial performed to date (N = 20,000).[117] Fondaparinux was found to be non-inferior to enoxaparin with respect to the clinical end point of 9-day death, MI or refractory ischemia (5.8% vs 5.7%, hazard ratio 1.01, 95% CI, 0.90–1.13). Fondaparinux also reduced the rate of major bleeding compared with enoxaparin (2.2% vs 4.1%, $P < 0.001$). At 30 days, mortality was lower in fondaparinux-treated patients (8.0 vs 8.6%, hazard ratio 0.83, 95% CI, 0.71–0.97), and the investigators suggested that the excess mortality observed in enoxaparin-treated patients was related to bleeding events. The major limitation of OASIS-5 is that only 30% of patients underwent PCI. In addition, the duration of study drug administration, (median of about 5 days) was longer than usual in the United States, which may have increased bleeding events. Supplemental doses of UFH were administered to patients randomized to enoxaparin who underwent PCI. For patients randomized to fondaparinux who underwent PCI, the protocol was changed. The original protocol specified that intravenous fondaparinux be administered to patients undergoing PCI. When this practice was associated with catheter thrombosis, the protocol was changed to recommend supplemental UFH be given (see Table 24–4 for recommendations) to fondaparinux-treated patients undergoing PCI. As a result, interventional cardiologists may be reluctant to use low-dose fondaparinux for patients undergoing PCI.

Bivalirudin is an IV direct thrombin inhibitor that has a short duration of action. When administered as a bolus and short infusion that is continued during the PCI procedure only, bivalirudin has been shown to lower bleeding risk compared with UFH and enoxaparin.

In the Acute Catheterization and Urgent Intervention Triage Strategy (ACUITY) trial 13,819 patients with NSTE ACS at moderate- to high-risk of death or MI (expected to undergo coronary angiography within the first 48 to 72 hours of hospital admission) were randomized to one of three antithrombotic treatment strategies: (1) heparin (UFH or enoxaparin) plus a glycoprotein (GP) IIb/IIIa inhibitor, (2) bivalirudin plus GP IIb/IIIa inhibitor, or (3) bivalirudin alone in a noninferiority trial (see Table 24–4 for dosing).[74] The primary end point was "net clinical outcome" at 30 days, which was a quadruple end point consisting of the composite ischemic end point (death, MI, or unplanned revascularization for ischemia) plus non-CABG major bleeding. The results of the quadruple end point were that bivalirudin alone was noninferior to bivalirudin plus a GP IIb/IIIa inhibitor and superior to heparin plus a GP IIb/IIIa inhibitor. The benefit of bivalirudin alone was that it reduced the rate of major bleeding by 47% compared with heparin plus a GP IIb/IIIa receptor inhibitor. Although numerically higher in the bivalirudin group, the ischemic end points were not statistically different between the groups.[74]

With similar efficacy and a lower bleeding rate, on the surface bivalirudin alone appears the preferred therapy. However, several issues surround the study design and application to practice. The main issue surrounds the noninferiority margin of 25% used in the trial. This means that bivalirudin could be 25% "worse" than heparin plus GPI treated and still be called *noninferior*. In fact, the upper boundary of the 95% CI for the ischemic composite end point comparing bivalirudin alone with heparin plus a GP IIb/IIIa inhibitor was 1.24.[74] Other contemporary NSTE ACS trials, have used lower margins. More than 60% of patients received on average more than 14 hours of prerandomized treatment prior to study enrollment and were "crossed over" to study medications. Study medications were administered for a median duration of less than 6 hours before coronary angiography and PCI, and the overall duration of study drug administration was less than 18 hours since most study drugs were discontinued after angiography. Therefore although patients were randomized, there was potential for the prerandomization therapy to impact study outcomes, and some could question whether the short duration of treatment was long enough to impact outcomes. So while bivalirudin is a choice for higher-risk patients with NSTE ACS anticipated to undergo angiography and PCI, it was not given a "preferred" recommendation in the 2007 NSTE ACS guidelines.[2,3]

Because LMWHs are eliminated renally and patients with renal insufficiency generally have been excluded from clinical trials, some practice protocols recommend UFH for patients with creatinine clearance rates of less than 30 mL/min. (Creatinine clearance is calculated based on total patient body weight using the Cockroft-Gault equation estimated using total body weight.[2,3]) However, while recommendations for dosing adjustment of enoxaparin for patients with creatinine clearance between 10 and 30 mL/min are listed in the product manufacturer's label, the safety and efficacy of LMWH in this patient population remain vastly understudied. Administration of LMWHs should be avoided in dialysis patients with ACS. It is unclear whether bivalirudin requires dose adjustment for patients with significant renal dysfunction. While bivalirudin is eliminated renally, the duration of infusion in recent trials has been short (several hours only), and therefore the actual need for dosing adjustment is unlikely.[74] Patients with serum creatinine greater than 3.0 mg/dL were excluded from ACS trials with fondaparinux, and the product label states that fondaparinux is contraindicated for patients with creatinine clearance <30 mL/min and for patients weighing less than 50 kg.

UFH is monitored and the dose adjusted to a target aPTT, whereas LMWHs are administered by a fixed, actual body weight-based dose without routine monitoring of antifactor Xa levels. Some experts recommend antifactor Xa monitoring for LMWHs for patients with renal impairment during prolonged courses of administration of more than several days.[118] No monitoring of coagulation is recommended for bivalirudin and fondaparinux.

Since there is a variety of anticoagulants recommended by the guidelines, practitioners should be familiar with the study designs, patient demographics, and results for recent NSTE ACS studies and develop protocols for dosing each agent that is on the hospital formulary. Dosing information and contraindications are described in Table 24–4.

Nitrates

For patients with ischemic chest discomfort, SL NTG, 0.4 mg every 5 minutes for a total of 3 doses should be administered. IV NTG should be administered to all patients with NSTE ACS with persistent ischemia, HF symptoms or hypertension in the absence of contraindications (see Table 24–4).[2] The mechanism of action, dosing, contraindications, and adverse effects are the same as described in the section Early Pharmacotherapy for STE MI. IV NTG typically is continued for approximately 24 hours following ischemia relief. The mechanism of action, dosing, contraindications, and adverse effects are the same as described in the section Early Pharmacotherapy for STE MI.

β-Blockers

Oral β-blockers should be administered to all patients with NSTE ACS prior to hospital discharge in the absence of contraindications.[2] IV β-blockers should be considered in hemodynamically stable patients who present with persistent ischemia, hypertension, or tachycardia. The mechanism of action, dosing, contraindications, and adverse effects are the same as described in the section Early Pharmacotherapy for ST-Segment Elevation ACS. β-Blockers are continued indefinitely.

Calcium Channel Blockers

As previously described, calcium channel blockers should not be administered to most patients with ACS.[2] Their role is a second-line treatment for patients with certain contraindications to β-blockers and those with continued ischemia despite β-blocker and nitrate therapy. They are a first-line therapy for patients with Prinzmetal vasospastic angina and those with cocaine-associated ACS. Administration of amlodipine, diltiazem, or verapamil is preferred.[2] Agent selection based on heart rate and LV dysfunction (diltiazem and verapamil contraindicated for patients with bradycardia, heart block, or systolic HF) is described in more detail in the section Early Pharmacotherapy for ST-Segment Elevation ACS. Dosing and contraindications are described in Table 24–4.

Glycemic Control

While there are numerous guidelines and standards addressing the management of diabetes mellitus in the outpatient setting, only recently has there been sufficient evidence to warrant the development of standards of care to optimize inpatient glycemic control for hospitalized individuals with diabetes or illness-induced hyperglycemia. In 2004, a joint practice guideline from the American Diabetes Association and the American College of Endocrinology recommend that the blood glucose level in critically ill patients, such as those with ACS, be kept as close to 110 mg/dL (6.1 mmol/L) as possible.[119] This was supported by the 2004 ACC/AHA STE MI guidelines that recommend normalization of blood glucose during the first 24 to 48 hours of care.[6] Elevated blood glucose levels are associated with higher mortality rates and larger infarct size in patients with acute MI.[119] Beneficial outcomes that have been associated with "tight" glucose control in some trials of critically ill patients include reductions in the development of renal dysfunction, infections, and length of mechanical ventilation.[6,119] For patients with MI, glucose control has been associated with a reduction in inflammatory markers and improvement in LVEF.[5] More recently, results from a large international trial of more than 6,000 patients in either medical or surgical intensive care units, Normoglycemia in Intensive Care Evaluation—Survival Using Glucose Algorithm Regulation (NICE-SUGAR), revealed increased mortality in patients randomized to tight glucose control targeted to 80 to 108 mg/dL (mean achieved was 115 mg/dL) versus less than 180 mg/dL (mean achieved 144 mg/dL) thought secondary to an increased number of hypoglycemic events in the intensive-control group.[120] Therefore, in 2009, the ACC/AHA revised the practice guidelines to recommend a less intensive target of <180 mg/dL for patients with STEMI, often achieved using an insulin-based regimen while avoiding episodes of hypoglycemia.[5]

SECONDARY PREVENTION FOLLOWING MI

The long-term goals following MI are to

1. Control modifiable CHD risk factors
2. Prevent the development of systolic HF
3. Prevent recurrent MI and stroke
4. Prevent death, including sudden cardiac death

9 Pharmacotherapy that has been proven to decrease mortality, HF, reinfarction, or stroke should be initiated prior to hospital discharge for secondary prevention. Guidelines from the ACC/AHA suggest that following MI from either STE or NSTE ACS patients should receive indefinite treatment with aspirin, a β-blocker, and an ACE inhibitor (or alternatively and ARB).[2,3,6] All patients should receive SL NTG or lingual spray and instructions for use in case of recurrent ischemic chest discomfort.[2,6] Clopidogrel or prasugrel should be considered for most patients, but the duration of therapy is individualized according to the type of ACS and whether the patient is treated medically or with PCI and whether a drug-eluting versus a bare-metal stent is placed.[2,5] All patients should receive annual influenza vaccination.[121,122] Select patients, such as those with atrial fibrillation, also will be treated with long-term warfarin anticoagulation, in addition to aspirin and a thienopyridine.[6] Eplerenone should be added to therapy with a β-blocker and an ACE inhibitor for patients with an LVEF less than 40%.[2,6,112] For all patients with ACS, treatment and control of modifiable risk factors such as hypertension, dyslipidemia, and diabetes mellitus are essential. Most patients with CHD will require drug therapy for dyslipidemia, usually with a statin (hydroxymethylglutaryl coenzyme A reductase inhibitor).[2,3] Benefits and adverse effects of long-term treatment with these medications are discussed in more detail in the following sections.

Aspirin

Aspirin decreases the risk of death, recurrent MI, and stroke following MI. An aspirin prescription at hospital discharge is a quality care indicator in MI patients[23] (see Table 24–3). The clinical value of aspirin in secondary prevention of ACS and other vascular diseases was demonstrated in a large number of clinical trials. Following an MI, aspirin is expected to prevent 36 vascular events per 1,000 patients treated for 2 years.[52,55] Because the benefit of antiplatelet agents appears to be sustained for at least 2 years following an MI,[55] all patients should receive aspirin indefinitely, or clopidogrel for patients with a contraindication to aspirin.[2–6]

Thienopyridines

For patients with ACS, clopidogrel and prasugrel decrease the risk of developing either death, MI, or stroke in patients post-PCI.[62,99] The benefit is primarily in reducing the rate of MI.[99] For patients with an STEMI treated medically without revascularization including PCI or CABG, clopidogrel can be given for 14 days and up to 1 year.[3] For patients in which an intracoronary stent was placed, clopidogrel and prasugrel should be continued for up to 12 months for patients at low risk of bleeding, with an option for up to 15 months of therapy for patients with a drug-eluting stent.[5]

The most common adverse effects for patients receiving clopidogrel and prasugrel are rash (approximately 5%) and diarrhea or gastrointestinal upset (approximately 3%).[58,59]

Anticoagulation

Warfarin should be considered in select patients following an ACS, including patients with a LV thrombus, patients demonstrating extensive ventricular wall motion abnormalities on cardiac echocardiogram, and patients with a history of thromboembolic disease or chronic atrial fibrillation.[3] An INR of 2.0 to 2.5 is recommended when warfarin is added to dual antiplatelet therapy with a thienopyridine.[3] Clopidogrel is preferred in such patients because the risk of bleeding with prasugrel is increased compared with

clopidogrel and the risk of bleeding with warfarin added to dual antiplatelet therapy is even greater. A more detailed discussion regarding the use of warfarin is available in Chap. 26.

β-Blockers, Nitrates, and Calcium Channel Blockers

Current treatment guidelines recommend that following an ACS, patients should receive a β-blocker indefinitely[2,3] whether they have residual symptoms of angina or not.[123] β-Blocker prescription at hospital discharge in the absence of contraindications is a quality performance measure (see Table 24–3).[23] Overwhelming data support the use of β-blockers for patients with a previous MI. Data from a systematic review of long-term trials of patients with recent MI demonstrate that the NNT for 1 year with a β-blocker to prevent one death is only 84 patients.[123] Because the benefit from β-blockers appears to be maintained for at least 6 years following an MI,[124] it is recommended that all patients receive β-blockers indefinitely in the absence of contraindications or intolerance.[2,3] Currently, there are no data to support the superiority of one β-blocker over another, although the only β-blocker with intrinsic sympathomimetic activity that has been shown to be beneficial following MI is acebutolol in one study of modest size.[125]

Although β-blockers should be avoided for patients with HF from LV systolic dysfunction complicating an MI, clinical trial data suggest that it is safe to initiate β-blockers prior to hospital discharge in these patients once HF symptoms have resolved.[126] These patients actually may benefit more than those without LV dysfunction.[127]

For patients who cannot tolerate or have a contraindication to a β-blocker, a calcium channel blocker can be used to prevent anginal symptoms but should not be used routinely in the absence of such symptoms.[2,3,128] Finally, all patients should be prescribed short-acting SL NTG or lingual NTG spray to relieve any anginal symptoms when necessary and should be instructed on its use.[2,3] Chronic long-acting nitrate therapy has not been shown to reduce CHD events following MI. Therefore, IV NTG is not followed routinely by chronic, long-acting oral nitrate therapy in ACS patients who have undergone revascularization unless the patient has chronic stable angina or significant coronary stenoses that were not revascularized.[128]

ACE Inhibitors and Angiotensin Receptor Blockers

ACE inhibitors should be initiated in all patients following MI to reduce mortality, decrease reinfarction, and prevent the development of HF.[2,3,121] Dosing and contraindications are described in Table 24–4. The benefit of ACE inhibitors and angiotensin receptor blockers (ARBs) for patients with MI most likely comes from their ability to prevent cardiac remodeling. Other proposed mechanisms include improvement in endothelial function, a reduction in atrial and ventricular arrhythmias, and promotion of angiogenesis, leading to a reduction in ischemic events. The largest reduction in mortality with ACE inhibitors is observed for patients with LV dysfunction (low LVEF) or HF symptoms.[129] Long-term studies in patients with LV systolic dysfunction with or without HF symptoms demonstrate greater benefit because mortality reductions are larger (23.4% vs 29.1%; $P<0.0001$) such that only 17 patients need treatment to prevent 1 death, with 57 lives saved for every 1,000 patients treated.[130] The use of ACE inhibitors in a wide range of patient types without a contraindication to ACE inhibitors may be expected to save 5 lives per 1,000 patients treated for 30 days.[129] ACE inhibitor prescription at hospital discharge following MI, in the absence of contraindications, to patients with depressed LV function (LVEF <40%) is currently a quality care indicator[23] (see Table 24–3).

Early initiation (within 24 hours) of an *oral* ACE inhibitor appears to be crucial during an acute MI because 40% of the 30-day survival benefit is observed during the first day, 45% from days 2 to 7, and approximately 15% from days 8 to 30.[129] However, data do not support the early administration of *intravenous* ACE inhibitors for patients experiencing an MI because mortality may be increased.[131] Hypotension should be avoided because coronary artery filling may be compromised. Because the benefits of ACE inhibitor administration have been documented out to 12 years following therapy for 2 to 4 years following MI for patients with LV dysfunction,[130,132] administration should continue indefinitely.

Additional data suggest that even patients with preserved LV function benefit from ACE inhibitors for secondary prevention as ACE inhibitors have demonstrated reductions in mortality, reinfarction, stroke, and development of HF.[133] Therefore all patients, and not just those with reduced LVEFs, should be considered for ACE inhibitor therapy prior to hospital discharge. However, ACE inhibitor prescription (or alternatively an ARB) at hospital discharge following MI, in the absence of contraindications, to patients with depressed LV function (LVEF less than 40%) is currently the only quality performance measure reported.[23] Similar outcomes have been demonstrated with both valsartan and candesartan for patients following myocardial infarction or with chronic HF compared with ACE inhibitors.[134,135]

Besides hypotension, the most frequent adverse reaction to an ACE inhibitor is cough, which may occur in up to 30% of patients. Patients with ACE inhibitor cough and either clinical signs of HF or LVEF less than 40% may be prescribed an ARB.[3] Other less common but more serious adverse effects of ACE inhibitors and ARBs include acute renal failure and hyperkalemia. While the incidence of angioedema appears higher for patients receiving ACE inhibitors (0.1% to 1.0% with an ACE inhibitor), ARBs have also been associated with angioedema, including recurrent angioedema in patients with a prior history of angioedema while receiving an ACE inhibitor.[136] Therefore, while ARBs are not contraindicated, the severity of angioedema while receiving an ACE inhibitor, for example, tongue or laryngeal edema necessitating intubation and mechanical ventilation, should be considered before starting an ARB for a patient with prior ACE inhibitor-associated angioedema.

Aldosterone Antagonists

Administration of an aldosterone antagonist, either eplerenone or spironolactone, should be considered within the first 2 weeks following MI in all patients already receiving an ACE inhibitor who experienced HF symptoms during hospitalization for MI and have an LVEF of 40% or less to reduce mortality.[3,121] Aldosterone plays an important role in HF and MI because it promotes vascular and myocardial fibrosis, endothelial dysfunction, hypertension, LV hypertrophy, sodium retention, potassium and magnesium loss, and arrhythmias. Aldosterone blockers have been shown in experimental and human studies to attenuate these adverse effects.[137] As discussed in Chap. 20, the benefit of aldosterone blockade for patients with stable, severe HF was highlighted in the Randomized Aldactone Evaluation Study (RALES), where spironolactone decreased the risk of all-cause mortality.[138]

Eplerenone, like spironolactone, is an aldosterone blocker that blocks the mineralocorticoid receptor. In contrast to spironolactone, eplerenone has no effect on the progesterone or androgen receptor, thereby minimizing the risk of gynecomastia, sexual dysfunction, and menstrual irregularities.[139] The Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) evaluated the effect of aldosterone antagonism for patients with an MI complicated by HF or LV dysfunction. Patients (n = 6,642) were randomized 3 to 14 days following the MI

to eplerenone or placebo.[139] Eplerenone significantly reduced the risk of mortality (14.4% vs 16.7%; $P = 0.008$). Data from EPHESUS suggest that eplerenone reduced mortality from sudden death, HF, and MI. Eplerenone also reduced the risk of hospitalizations for HF. Most patients in EPHESUS also were being treated with aspirin, a β-blocker, and an ACE inhibitor. Approximately half the patients also were receiving a statin. Therefore, the mortality reduction observed was in addition to that of standard therapy for secondary CHD prevention. These benefits were obtained at the expense of an increased risk of severe hyperkalemia (5.5% vs 3.9%; $P = 0.002$), defined as a potassium concentration equal or greater than 6 mEq/L. Patients with a serum creatinine concentration of greater than 2.5 mg/dL or a serum potassium concentration of greater than 5 mEq/L at baseline were excluded. The risk of hyperkalemia was particularly alarming for patients with a creatinine clearance of less than 50 mL/min. This highlights the importance of close monitoring of potassium level and renal function for patients being treated with eplerenone. There was no increase in gynecomastia, breast pain, or impotence.

The results from EPHESUS have raised the question of which aldosterone blocker, spironolactone or eplerenone, should be used preferentially. Currently, there are no data to support that the more selective, but more expensive eplerenone is superior to or should be preferred to the less expensive generic spironolactone unless a patient has experienced gynecomastia, breast pain, or impotence while receiving spironolactone. Finally, it should be noted that hyperkalemia is just as likely to appear with both these agents.

Lipid-Lowering Agents

There are now overwhelming data supporting the benefits of statins for patients with CAD in the prevention of total mortality, cardiovascular mortality, and stroke. According to the National Cholesterol Education Program (NCEP) Adult Treatment Panel recommendations, all patients with CAD should receive dietary counseling and pharmacologic therapy in order to reach an LDL cholesterol concentration of less than 100 mg/dL, with statins being the preferred agents to lower LDL cholesterol.[121,140,141] Although the primary effect of statins is to decrease LDL cholesterol, statins are believed to produce many non-lipid-lowering or "pleiotropic" effects. These effects, which include improvement in endothelial dysfunction, antiinflammatory and antithrombotic properties, and a decrease in matrix metalloproteinase activity, may be relevant for patients experiencing an ACS and result in short-term (<1 year) benefit. A meta-analysis of randomized, controlled clinical trials in almost 18,000 patients with recent ACS (<14 days) indicated that statin therapy reduces mortality by 19% with benefits observed after approximately 4 months of treatment.[142]

Recommendations from the NCEP give an optional goal of an LDL cholesterol of less than 70 mg/dL for secondary prevention.[2,141] This recommendation is based upon a large clinical trial evaluating recurrence of major cardiovascular events in patients with a history of an ACS occurring within the past 10 days. This trial documented the benefit of lowering LDL cholesterol to, on average, 62 mg/dL, with 80 mg of atorvastatin compared with 95 mg/dL for patients treated with pravastatin 40 mg daily.[143] Whether a statin should be used routinely in all patients irrespective of their baseline LDL cholesterol level is currently being investigated, but preliminary data from the Heart Protection Study suggest that patients benefit from statin therapy irrespective of their baseline LDL cholesterol level.[144] The 2007 ACC/AHA NSTE ACS guidelines recommended statin therapy, in addition to diet, for all ACS patients, regardless of LDL cholesterol level, although the exact target LDL, if the patient's LDL cholesterol at hospital presentation is already less than 70 mg/dL, is not stated.[2]

A fibrate or niacin may be considered in select patients with a low high-density lipoprotein (HDL) cholesterol concentration (<40 mg/dL) and/or a high triglyceride level (>200 mg/dL).[2,121,141] In a large, randomized trial in men with established CAD and low levels of HDL cholesterol, the use of gemfibrozil (600 mg twice daily) significantly decreased the risk of nonfatal MI or death from coronary causes.[145] No such benefit was observed with fenofibrate in two large multicenter primary and secondary prevention studies for patients with diabetes mellitus.[146,147] However, due to the increased risk of myopathy, gemfibrozil is not recommended for patients receiving a statin.

Additional discussion, dosing, monitoring, and adverse effects of using lipid-lowering drugs for secondary prevention may be found in Chap. 28.

Fish Oils (Marine-Derived Omega-3 Fatty Acids)

Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are omega-3 polyunsaturated fatty acids that are most abundant in fatty fish such as sardines, salmon, and mackerel. Epidemiologic and randomized trials have demonstrated that a diet high in EPA plus DHA or supplementation with these fish oils reduces the risk of cardiovascular mortality, reinfarction, and stroke in patients who have experienced an MI.[148] Although the exact mechanism responsible for the beneficial effects of omega-3 fatty acids has not been clearly elucidated, potential mechanisms include triglyceride-lowering effects, antithrombotic effects, retardation in the progression of atherosclerosis, endothelial relaxation, mild antihypertensive effects, and reduction in ventricular arrhythmias.[148]

The GISSI-Prevenzione trial, the largest randomized trial of fish oils published to date, evaluated the effects of open-label EPA plus DHA (LOVAZA) in 11,324 patients with recent MI who were randomized to receive 850 to 882 mg/day of n-3 polyunsaturated fatty acid (EPA plus DHA) in a ratio of EPA:DHA of 1.2:1, 300 mg vitamin E, both, or neither.[149,150] The use of EPA plus DHA reduced the risk of death, nonfatal acute MI, or nonfatal stroke, whereas the use of vitamin E had no significant impact on this combined clinical end point. Therefore, based on current data, the AHA recommends that CHD patients consume approximately 1 g EPA plus DHA per day, preferably from oily fish.[121,148] Because oil content in fish varies, the number of 6-oz servings of fish that would need to be consumed to provide 7 g EPA plus DHA per week varies from approximately 4 to more than 14 for secondary prevention. The average diet only contains one-tenth to one-fifth the recommended amount.[148] Supplements could be considered for select patients who do not eat fish, have limited access to fish, or who cannot afford to purchase fish. Approximately three 1 g fish oil capsules per day should be consumed to provide 1 g omega-3 fatty acids depending on the brand of supplement.[148] Alternatively, the prescription drug, LOVAZA may be used in a dose of 1 g/day. Finally, current guidelines suggest that higher doses of EPA plus DHA (2 to 4 g/day) also can be considered for the management of hypertriglyceridemia.[2,121,148] Adverse effects from fish oils include fishy aftertaste, nausea, and diarrhea.[148]

Other Modifiable Risk Factors

Smoking cessation, control of hypertension, weight loss, and tight glucose control for patients with diabetes mellitus, in addition to treatment of dyslipidemia, are important treatments for secondary prevention of CHD events.[3,121] All patients with CAD should receive annual influenza vaccination.[121,122] Influenza-related deaths are highest among patients with CVD compared with patients with other medical conditions.[122] Annual influenza vaccination has been shown in randomized controlled clinical trials to reduce

CV mortality and MI.[122] Smoking cessation is accompanied by a significant reduction in all-cause mortality in patients with CAD.[151] Smoking cessation counseling at the time of discharge following MI is a quality care indicator[23] (see Table 24–3). The use of nicotine patches or gum, bupropion alone or in combination with nicotine patches, or varenicline should be considered in appropriate patients.[3] Following MI, hypertension should be strictly controlled to a target blood pressure of <140/90 according to the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure guidelines.[152] Patients who are overweight should be educated on the importance of regular exercise, healthy eating habits, and of reaching and maintaining an ideal weight.[153] Finally, because diabetics have up to a fourfold increased risk of mortality compared with nondiabetics, the importance of glucose control, as well as other CHD risk factor modification, cannot be understated.

MEDICATION ADHERENCE AND PERSISTENCE

It is becoming increasingly clear that medication nonadherence poses a problem for patients following ACS. Indeed, it is estimated that almost 7% of patients do not fill prescriptions for thienopyridines following hospitalization for PCI and stent placement.[154] Approximately 15% do not fill prescriptions for β-blockers following discharge following MI, and persistence is only 60% at 6 months.[155] Primary nonadherence at 120 days following discharge for MI was 26% in one large study of 4,591 patients >65 years of age.[156] Medication discontinuation has been associated with an increased risk of CV events and mortality in patients with various types of CVD.[156–159] In clinical trials, poor adherence is associated with poor outcome, regardless of treatment assignment,[159] highlighting that this behavior may be related with other health-related behaviors in patients. Increased adherence to statins and β-blockers has been associated with lower long-term mortality.[160]

The discontinuation of thienopyridines may be particularly problematic for patients treated with a drug-eluting stent,[161] because this places the patient at an increased risk for stent thrombosis and increased mortality.[72,154] Current data suggest that long-term adherence and persistence to statins for patients with an ACS and for patients with chronic CAD is variable.[162–165] Persistence to statins is associated with lower risk of MI.[166] Early initiation of statins for patients with ACS appears to increase long-term persistence with statin therapy, which should result in clinical benefit.[142] Therefore, for patients with an ACS, statin therapy initiation should not be delayed, and statins should be prescribed at or prior to discharge in most patients.

Several clinical trials have documented the value of a pharmacist in the management in improving adherence and persistence to medication, which in turn can significantly improve the treatment of risk factors such as hypertension, HF, and dyslipidemia.[167,168]

PHARMACOECONOMIC CONSIDERATIONS

The risks of CHD events, such as death, recurrent MI, and stroke, are higher for patients with established CHD and a history of MI than for patients with no known CHD. Because the costs for chronic preventative pharmacotherapy are the same for primary and secondary prevention, while the risk of events is higher with secondary prevention, secondary prevention is more cost-effective than primary prevention of CHD.[169] Pharmacotherapy that has demonstrated cost-effectiveness to prevent death in the ACS and post-MI patient includes fibrinolytics ($2,000 to $33,000 cost per year of life saved),[169,170] aspirin[171], glycoprotein IIb/IIIa receptor blockers ($ 13,700 to $16,500 per year of life added),[172] β-blockers (less than $5,000 to $15,000 cost per year of life saved),[173] ACE inhibitors ($3,000 to $5,000 cost per year of life saved),[174,175] eplerenone ($15,300 to $32,400 per life year gained),[176] statins ($4,500 to $9,500 per year of life saved),[177] gemfibrozil ($17,000 per year of life saved),[178] and fish oil.[179] The cost-effectiveness of prasugrel compared with clopidogrel is $9,727 per year of life gained based upon data from the TRITON-TIMI 28 trial.[180] Because cost-effectiveness ratios of less than $50,000 per added life-year are considered economically attractive from a societal perspective,[169] pharmacotherapy above for ACS and secondary prevention are standards of care because of their efficacy and cost-attractiveness to payers.

EVALUATION OF THERAPEUTIC OUTCOMES

The monitoring parameters for *efficacy* of nonpharmacologic and pharmacotherapy for both STE MI and NSTE ACS are similar:

- Relief of ischemic discomfort
- Return of ECG changes to baseline
- Absence or resolution of HF signs

Monitoring parameters for recognition and prevention of *adverse effects* from ACS pharmacotherapy are described in Table 24–6. In general, the most common adverse reactions from ACS therapies are hypotension and bleeding. Treatment for bleeding and hypotension involves discontinuation of the offending agent(s) until symptoms resolve. Severe bleeding resulting in hypotension secondary to hypovolemia may require blood transfusion.

CONCLUSIONS

The AHA and ACC published evidence-based practice guidelines for the treatment of patients with STE and NSTE ACS. Mainstays of therapy include risk stratification, primary PCI for STE MI, early angiography and revascularization with either PCI or CABG for patients with NSTE ACS at high risk of MI and death. Pharmacotherapy for acute treatment includes sublingual NTG, antiplatelets, and anticoagulants. Routine pharmacotherapy for secondary prevention of recurrent ACS, MI, and CHD death includes aspirin, a thienopyridine, statin, β-blocker and either an ACE inhibitor or an ARB. Ensuring selection of evidence-based therapies for all patients without contraindications results in lower mortality. Encouraging adherence and persistence of pharmacotherapy is also important role for pharmacists.

ABBREVIATIONS

ACC: American College of Cardiology

ACE: angiotensin-converting enzyme

ACS: acute coronary syndrome

ACT: activated clotting time

ACTION: Acute Coronary Treatment and Interventions Network

ACUITY: Acute Catheterization and Urgent Intervention Triage Strategy

ADP: adenosine diphosphate

AHA: American Heart Association

aPTT: activated partial thromboplastin time

ARB: angiotensin receptor blocker

TABLE 24-6 Therapeutic Drug Monitoring for Adverse Effects of Pharmacotherapy for Acute Coronary Syndromes

Drug	Adverse Effects	Monitoring
Aspirin	Dyspepsia, bleeding, gastritis	Clinical signs of bleeding,[a] gastrointestinal upset; baseline CBC and platelet count; CBC platelet count every 6 months
Clopidogrel and prasugrel	Bleeding, diarrhea, rash, TTP (rare)	Clinical signs of bleeding[a]; baseline CBC and platelet count; CBC and platelet count every 6 months following hospital discharge
Unfractionated heparin	Bleeding, heparin-induced thrombocytopenia	Clinical signs of bleeding[a]; baseline aPTT, INR, CBC and platelet count; aPTT every 6 hours until target then every 24 hours; daily CBC; platelet count every 2–3 days from day 4 to 14 until heparin is stopped (minimum, preferably every day)
Enoxaparin	Bleeding, heparin- induced thrombocytopenia	Clinical signs of bleeding[a]; baseline SCr, aPTT, INR, CBC and platelet count; daily CBC, no routine platelet count monitoring unless recent UFH (less than 100 days) then baseline and within 24 hours; daily CBC and SCr
Fondaparinux	Bleeding	Clinical signs of bleeding[a]; baseline SCr, aPTT, INR, CBC and platelet count; daily CBC and SCr
Bivalirudin	Bleeding	Clinical signs of bleeding[a]; baseline SCr, aPTT, INR, CBC and platelet count; daily CBC and SCr
Fibrinolytics	Bleeding, especially intracranial hemorrhage	Clinical signs of bleeding[a]; baseline aPTT, INR, CBC and platelet count; mental status every 2 hours for signs of intracranial hemorrhage; daily CBC
Glycoprotein IIb/IIIa receptor blockers	Bleeding, acute profound thrombocytopenia	Clinical signs of bleeding[a]; baseline SCr (for eptifibatide and tirofiban), CBC, and platelet count; platelet count at 4 hours after initiation; daily CBC (and SCr for eptifibatide and tirofiban)
Intravenous nitrates	Hypotension, flushing, headache, tachycardia	BP and HR every 2 hours
β-Blockers	Hypotension, bradycardia, heart block, bronchospasm, acute heart failure, fatigue, depression, sexual dysfunction	BP, RR, HR, 12-lead ECG and clinical signs of heart failure every 5 minutes during bolus intravenous dosing; BP, RR, HR, and clinical signs of heart failure every shift during oral administration during hospitalization, then BP and HR every 6 months following hospital discharge
Diltiazem and verapamil	Hypotension, bradycardia, heart block, heart failure, gingival hyperplasia	BP and HR every shift during oral administration during hospitalization then every 6 months following hospital discharge; dental exam and teeth cleaning every 6 months
Amlodipine	Hypotension, dependent peripheral edema, gingival hyperplasia	BP every shift during oral administration during hospitalization, then every 6 months following hospital discharge; dental exam and teeth cleaning every 6 months
Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs)	Hypotension, cough (with ACE inhibitors), hyperkalemia, prerenal azotemia, acute renal failure, angioedema (ACE inhibitors more so than ARBs)	BP every 2 hours × 3 for first dose, then every shift during oral administration during hospitalization, then once every 6 months following hospital discharge; baseline SCr and potassium; daily SCr and potassium while hospitalized then every 6 months (or 1–2 weeks after each outpatient dose titration); closer monitoring required in selected patients using spironolactone or eplerenone or if renal insufficiency; counsel patient on throat, tongue, and facial swelling
Aldosterone antagonists	Hypotension, hyperkalemia	BP and HR every shift during oral administration during hospitalization, then once every 6 months; baseline SCr and serum potassium concentration; SCr and potassium at 48 hours, at 7 days, then monthly for 3 months, then every 3 months thereafter following hospital discharge
Warfarin	Bleeding, skin necrosis	Clinical signs of bleeding[a]; baseline CBC and platelet count; CBC and platelet count every 6 months following hospital discharge; baseline aPTT and INR; daily INR until two consecutive INRs are within the target range then once weekly × 2 weeks, then every month; See Chapter 26 for patient counseling points
Morphine	Hypotension, respiratory depression	BP and RR 5 minutes after each bolus dose
Statins	Gastrointestinal upset, myopathy, hepatotoxicity	Liver function tests at baseline, at 6 weeks following initiation, and after titration to highest dose, then annually thereafter; counsel patient on myalgia; consider creatinine kinase at baseline if adding a fibrate or niacin

[a] Clinical signs of bleeding include bloody stools, melena, hematuria, hematemesis, bruising, and oozing from arterial or venous puncture sites.
ACE, angiotensin-converting enzyme; aPTT, activated partial thromboplastin time; ARB, angiotensin receptor blocker; BP, blood pressure; CBC, complete blood count; ECG, electrocardiogram; HR, heart rate; INR, International Normalized Ratio; RR, respiratory rate; SCr, serum creatinine, TTP, thrombotic thrombocytopenic purpura.

AV: atrioventricular

CABG: coronary artery bypass graft

CAD: coronary artery disease

CBC: complete blood count

CHD: coronary heart disease

CK: creatine kinase

CK-MB: creatine kinase myocardial band

CREDO: Clopidogrel for the Reduction of Events During Observation

CURE: Clopidogrel in Unstable Angina to Prevent Recurrent Events

CVD: cardiovascular disease

DHA: docosahexaenoic acid

ECG: electrocardiogram

EPA: eicosapentaenoic acid

CHAPTER 25

The Arrhythmias

CYNTHIA A. SANOSKI AND JERRY L. BAUMAN

KEY CONCEPTS

1. The use of antiarrhythmic drugs (AADs) in the United States has declined because of major trials that show increased mortality with their use in several clinical situations, the realization of proarrhythmia as a significant side effect, and the advancing technology of nonpharmacologic therapies such as ablation and the implantable cardioverter-defibrillator (ICD).
2. AADs frequently cause side effects and are complex in their pharmacokinetic characteristics. Close monitoring is required of all of these drugs to assess for adverse effects as well as potential drug interactions.
3. The most commonly prescribed AAD is now amiodarone. This drug is effective in terminating and preventing a wide variety of symptomatic supraventricular and ventricular arrhythmias. However, because this AAD is plagued by frequent side effects, it requires close monitoring. The most concerning toxicity is pulmonary fibrosis; side effect profiles of the intravenous (IV) (acute, short-term) and oral (chronic, long-term) forms of amiodarone differ substantially.
4. In patients with artial fibrillation (AF), therapy is traditionally aimed at controlling ventricular rate (digoxin, nondihydropyridine [non-DHP] calcium channel blockers [CCBs], β-blockers), preventing thromboembolic complications (warfarin, aspirin), and restoring and maintaining sinus rhythm (SR) (AADs, direct-current cardioversion [DCC]). Studies show there is no need to aggressively pursue strategies to maintain SR (i.e., long-term AAD therapy); rate control alone (leaving the patient in AF) is often sufficient in patients who can tolerate it. Nonetheless, chronic AAD therapy may still be needed in patients who continue to have symptoms despite adequate ventricular rate control.
5. Paroxysmal supraventricular tachycardia (PSVT) is usually a result of reentry in or proximal to the atrioventricular (AV) node or AV reentry incorporating an extranodal pathway; common tachycardias can be terminated acutely with AV nodal-blocking drugs such as adenosine, and recurrences can be prevented by ablation with radiofrequency current.
6. Patients with Wolff-Parkinson-White (WPW) syndrome may have several different tachycardias that are acutely treated by different strategies: orthodromic reentry (adenosine), antidromic reentry (adenosine or procainamide), and AF (procainamide or amiodarone). AV nodal-blocking drugs are contraindicated in patients with WPW and AF.
7. Because of the results of the Cardiac Arrhythmia Suppression Trial (CAST) and other trials, AADs (with the exception of β-blockers) should not be routinely used in patients with prior myocardial infarction (MI) or left ventricular (LV) dysfunction and minor ventricular rhythm disturbances (e.g., premature ventricular complexes [PVCs]).
8. Patients with hemodynamically significant ventricular tachycardia (VT) or ventricular fibrillation (VF) not associated with an acute MI who are successfully resuscitated (electrical cardioversion, vasopressors, amiodarone) are at high risk for sudden cardiac death (SCD) and should receive an ICD ("secondary prevention").
9. Implantation of an ICD should be considered for the primary prevention of SCD in certain high-risk patient populations. High-risk patients include those with a history of MI and LV dysfunction (regardless of whether they have inducible sustained ventricular arrhythmias), as well as those with New York Heart Association (NYHA) class II or III heart failure (HF) as a result of either ischemic or nonischemic causes.
10. Life-threatening ventricular proarrhythmia generally takes two forms: sinusoidal or incessant monomorphic VT (class Ic AADs) and torsades de pointes (TdP) (class Ia or III AADs and many other noncardiac drugs).

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

The heart has two basic properties, namely an electrical property and a mechanical property. The synchronous interaction between these two properties is complex, precise, and relatively enduring. The study of the electrical properties of the heart has grown at a steady rate, interrupted by periodic salvos of scientific breakthroughs. Einthoven's pioneering work allowed graphic electrical tracings of cardiac rhythm and probably represents the first of these breakthroughs. This discovery of the surface electrocardiogram (ECG) has remained the cornerstone of diagnostic tools for cardiac rhythm disturbances. Since then, intracardiac recordings and programmed cardiac stimulation have advanced our understanding of arrhythmias, and microelectrode, voltage-clamping, and patch-clamping techniques have allowed considerable insight into the electrophysiologic actions and mechanisms of AADs. Certainly, the new era of molecular biology and mapping of the human genome promises even greater insights into mechanisms (and potential therapies) of arrhythmias. Noteworthy in this regard is the discovery of genetic abnormalities in the ion channels that control electrical repolarization (heritable long QT syndrome) or depolarization (Brugada syndrome).

The clinical use of drug therapy started with the use of digitalis and then quinidine. A surge of new agents followed somewhat later

in the 1980s. A theme of drug discovery during this decade was initially to find orally absorbed lidocaine congeners (such as mexiletine and tocainide); later, the emphasis was on drugs with extremely potent effects on conduction (i.e., flecainide-like agents). The most recent focus of investigational AADs are the potassium channel blockers, with dronedarone being the most recently approved AAD in the United States in nearly a decade. Previously, there was some expectation that advances in AAD discovery would lead to a highly effective and nontoxic agent that would be effective for a majority of patients (i.e., the so-called magic bullet). Instead, significant problems with drug toxicity and proarrhythmia have resulted in a decline in the overall volume of AAD usage in the United States since 1989. [1] The other phenomenon that has significantly contributed to the decline in AAD utilization is the development of extremely effective nonpharmacologic therapies. Technical advances have made it possible to permanently interrupt reentry circuits with radiofrequency ablation, which renders long-term AAD use unnecessary in certain arrhythmias. Furthermore, the impressive survival data associated with the use of ICDs for the primary and secondary prevention of SCD has led most clinicians to choose "device" therapy as the first-line treatment for patients who are at high risk for life-threatening ventricular arrhythmias. Both of these nonpharmacologic therapies have become increasingly popular for the management of arrhythmias so that the potential proarrhythmic effects and organ toxicities associated with AADs can be avoided.

This chapter reviews the principles involved in both normal and abnormal cardiac conduction and addresses the pathophysiology and treatment of the more commonly encountered arrhythmias. Certainly, many volumes of complete text could be (and have been) devoted to basic and clinical electrophysiology. Consequently, this chapter briefly addresses those principles necessary for clinicians.

ARRHYTHMOGENESIS

NORMAL CONDUCTION

Electrical activity is initiated by the sinoatrial (SA) node and moves through cardiac tissue by a treelike conduction network. The SA node initiates cardiac rhythm under normal circumstances because this tissue possesses the highest degree of automaticity or rate of spontaneous impulse generation. The degree of automaticity of the SA node is largely influenced by the autonomic nervous system in that both cholinergic and sympathetic innervations control the sinus rate. Most tissues within the conduction system also possess varying degrees of inherent automatic properties. However, the rates of spontaneous impulse generation of these tissues are less than that of the SA node. Thus these latent automatic pacemakers are continuously overdriven by impulses arising from the SA node (primary pacemaker) and do not become clinically apparent.

From the SA node, electrical activity moves in a wave front through an atrial specialized conducting system and eventually gains entrance to the ventricle via the AV node and a large bundle of conducting tissue referred to as the bundle of His. Aside from this AV node–bundle of His pathway, a fibrous AV ring that will not permit electrical stimulation separates the atria and ventricles. The conducting tissues bridging the atria and ventricles are referred to as the junctional areas. Again, this area of tissue (junction) is largely influenced by autonomic input and possesses a relatively high degree of inherent automaticity (about 40 beats/min, less than that of the SA node). From the bundle of His, the cardiac conduction system bifurcates into several (usually three) bundle branches: one right bundle and two left bundles. These bundle branches further arborize into a conduction network referred to as the Purkinje system. The conduction system as a whole innervates the mechanical myocardium and serves to initiate excitation–contraction coupling and the contractile process. After a cell or group of cells within the heart is electrically stimulated, a brief period of time follows in which those cells cannot again be excited. This time period is referred to as the refractory period. As the electrical wavefront moves down the conduction system, the impulse eventually encounters tissue refractory to stimulation (recently excited) and subsequently dies out. The SA node subsequently recovers, fires spontaneously, and begins the process again.

Prior to cellular excitation, an electrical gradient exists between the inside and the outside of the cell membrane. At this time, the cell is polarized. In atrial and ventricular conducting tissue, the intracellular space is approximately 80 to 90 mV negative with respect to the extracellular environment. The electrical gradient just prior to excitation is referred to as the resting membrane potential (RMP) and is the result of differences in ion concentrations between the inside and the outside of the cell. At RMP, the cell is polarized primarily by the action of active membrane ion pumps, the most notable of these being the sodium-potassium pump. For example, this specific pump (in addition to other systems) attempts to maintain the intracellular sodium concentration at 5 to 15 mEq/L and the extracellular sodium concentration at 135 to 142 mEq/L; the intracellular potassium concentration at 135 to 140 mEq/L and the extracellular potassium concentration at 3 to 5 mEq/L. The RMP can be calculated by using the Nernst equation:

$$\text{RMP} = 61.5 \log\left(\frac{[K^+] \text{ outside}}{[K^+] \text{ inside}}\right)$$

Electrical stimulation (or depolarization) of the cell will result in changes in membrane potential over time or a characteristic action potential curve (Fig. 25–1). The action potential curve results from the transmembrane movement of specific ions and is divided into different phases. Phase 0 or initial, rapid depolarization of atrial and ventricular tissues is caused by an abrupt increase in the permeability of the membrane to sodium influx. This rapid depolarization more than equilibrates (overshoots) the electrical potential, resulting in a brief initial repolarization or phase 1. Phase 1 (initial depolarization) is caused by a transient and active potassium efflux (i.e., the I_{Kto} current). Calcium begins to move into the intracellular space at about −60 mV (during phase 0), causing a slower depolarization. Calcium influx continues throughout phase 2 of the action potential (plateau phase) and is balanced to some degree by potassium efflux. Calcium entrance (only through L channels in myocardial tissue) distinguishes cardiac conducting cells from nerve tissue and provides the critical ionic link to excitation–contraction coupling and the mechanical properties of the heart as a pump. The membrane remains permeable to potassium efflux during phase 3, resulting in cellular repolarization. Phase 4 of the action potential is the gradual depolarization of the cell and is related to a constant sodium leak into the intracellular space balanced by a decreasing (over time) efflux of potassium. The slope of phase 4 depolarization determines, in large part, the automatic properties of the cell. As the cell is slowly depolarized during phase 4, an abrupt increase in sodium permeability occurs, allowing the rapid cellular depolarization of phase 0. The juncture of phase 4 and phase 0 where rapid sodium influx is initiated is referred to as the threshold potential of the cell. The level of threshold potential also regulates the degree of cellular automaticity.

Not all cells in the cardiac conduction system rely on sodium influx for initial depolarization. Some tissues depolarize in response to a slower inward ionic current caused by calcium influx. These "calcium-dependent" tissues are found primarily in the SA and AV nodes (both L and T channels) and possess distinct conduction properties in comparison to "sodium-dependent" fibers.

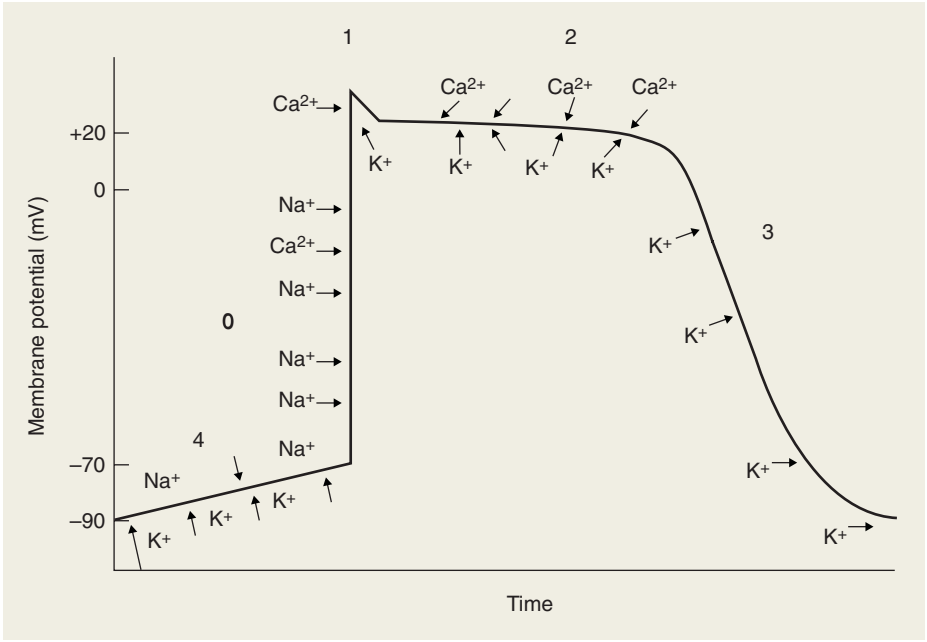

FIGURE 25-1. Purkinje fiber action potential showing specific ion flux responsible for the change in membrane potential. Ions outside of the line (e.g., sodium) move from the extracellular space to the intracellular space and ions on the inside of the line (e.g., potassium) move from the inside of the cell to the outside. Below the line is the corresponding ventricular excitation and recovery from the surface electrocardiogram. One can see that excessive sodium channel blockade from drugs may lead to QRS prolongation and excessive potassium channel blockade from drugs may lead to QT interval prolongation.

Calcium-dependent cells generally have a less negative RMP (−40 to −60 mV) and a slower conduction velocity. Furthermore, in calcium-dependent tissues, recovery of excitability outlasts full repolarization, whereas in sodium-dependent tissue, recovery is prompt after repolarization. These two types of electrical fibers also differ dramatically in how drugs modify their conduction properties.

Ion conductance across the lipid bilayer of the cell membrane occurs via the formation of membrane pores or "channels" (Fig. 25–2). Selective ion channels probably form in response to specific electrical potential differences between the inside and the outside of the cell (voltage dependence). The membrane itself is composed of both organized and disorganized lipids and phospholipids in a dynamic sol-gel matrix. During ion flux and electrical excitation, changes in this sol-gel equilibrium occur and permit the formation of activated ion channels. Besides channel formation and membrane composition, intrachannel proteins or phospholipids, referred to as gates, also regulate the transmembrane movement of ions. These gates are thought to be positioned strategically within the channel to modulate ion flow (Fig. 25–2). Each ion channel conceptually has two types of gates: an activation gate and an inactivation gate. The activation gate opens during depolarization to allow the ion current to enter or exit from the cell, and the inactivation gate later closes to stop ion movement. When the cell is in a rested state, the activation gates are closed and the inactivation gates are open. The activation gates then open to allow ion movement through the channel, and the inactivation gates later close to stop ion conductance. Thus the cell cycles between three states: resting, activated or open, and inactivated or closed. Activation of SA and AV nodal tissue is dependent on a slow depolarizing current through calcium channels and gates, whereas the activation of atrial and ventricular tissue is dependent on a rapid depolarizing current through sodium channels and gates.

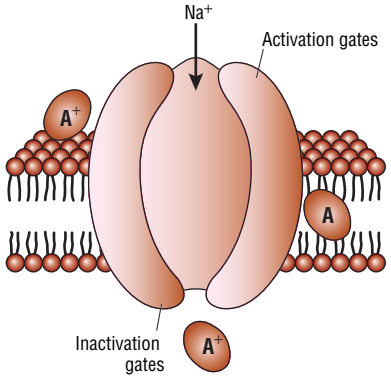

FIGURE 25-2. Lipid bilayer, sodium channel, and possible sites of action of the class I AADs (*A*). Class I AADs may theoretically inhibit sodium influx at an extracellular, intramembrane, or intracellular receptor site. However, all approved agents appear to block sodium conductance at a single receptor site by gaining entrance to the interior of the channel from an intracellular route. Active ionized drugs block the channel predominantly during the activated or inactivated state and bind and unbind with specific time constants (described as fast on-off, slow on-off, and intermediate) (AADs, antiarrhythmic drugs).

ABNORMAL CONDUCTION

The mechanisms of tachyarrhythmias have been classically divided into two general categories: those resulting from an abnormality in impulse generation or "automatic" tachycardias and those resulting from an abnormality in impulse conduction or "reentrant" tachycardias.

Automatic tachycardias depend upon spontaneous impulse generation in latent pacemakers and may be a result of several different mechanisms. Drugs, such as digoxin or catecholamines, and conditions, such as hypoxia, electrolyte abnormalities (e.g., hypokalemia), and fiber stretch (cardiac dilation), may lead to an increased slope of phase 4 depolarization in cardiac tissues other than the SA node. These factors that experimentally lead to abnormal automaticity are also known to be arrhythmogenic in clinical situations. The increased slope of phase 4 causes heightened automaticity of these tissues and competition with the SA node for dominance of cardiac rhythm. If the rate of spontaneous impulse generation of the abnormally automatic tissue exceeds that of the SA node, then an automatic tachycardia may result. Automatic tachycardias have the following characteristics: (a) the onset of the tachycardia is unrelated to an initiating event such as a premature beat; (b) the initiating beat is usually identical to subsequent beats

of the tachycardia; (c) the tachycardia cannot be initiated by programmed cardiac stimulation; and (d) the onset of the tachycardia is usually preceded by a gradual acceleration in rate and termination is usually preceded by a gradual deceleration in rate. Clinical tachycardias resulting from the classic forms of enhanced automaticity already described are not as common as once thought. Examples are sinus tachycardia and junctional tachycardia.

Triggered automaticity is also a possible mechanism for abnormal impulse generation. Briefly, triggered automaticity refers to transient membrane depolarizations that occur during repolarization (early after-depolarizations [EADs]) or after repolarization (late after-depolarizations [LADs]) but prior to phase 4 of the action potential. After-depolarizations may be related to abnormal calcium and sodium influx during or just after full cellular repolarization. Experimentally, EADs may be precipitated by hypokalemia, class Ia AADs, or slow stimulation rates—any factor that blocks the ion channels (e.g., potassium) responsible for cellular repolarization. EADs provoked by drugs that block potassium conductance and delay repolarization are the underlying cause of TdP. LADs may be precipitated by digoxin or catecholamines and suppressed by CCBs, and have been suggested as the mechanism for multifocal atrial tachycardia, digoxin-induced tachycardias and exercise-provoked VT. Triggered automatic rhythms possess some of the characteristics of automatic tachycardias and some of the characteristics of reentrant tachycardias (description follows).

As previously mentioned, the impulse originating from the SA node in an individual with SR eventually meets previously excited and thus refractory tissue. Reentry is a concept that involves indefinite propagation of the impulse and continued activation of previously refractory tissue. There are three conduction requirements for the formation of a viable reentrant focus: two pathways for impulse conduction, an area of unidirectional block (prolonged refractoriness) in one of these pathways, and slow conduction in the other pathway (Fig. 25–3). Usually a critically timed premature beat initiates reentry. This premature impulse enters both conduction pathways but encounters refractory tissue in one of the pathways at the area of unidirectional block. The impulse dies out because the tissue is still refractory from the previous (sinus) impulse. Although it fails to propagate in one pathway, the impulse may still proceed in a forward direction (antegrade) through the other pathway because of this pathway's relatively shorter refractory period. The impulse may then proceed through a loop of tissue and "reenter" the area of unidirectional block in a backward direction (retrograde). Because the antegrade pathway has slow conduction characteristics, the area of unidirectional block has time to recover its excitability. The impulse can proceed in a retrograde fashion through this (previously refractory) tissue and continue around the loop of tissue in a circular fashion. Thus, the key to the formation of a reentrant focus is crucial conduction discrepancies in the electrophysiologic characteristics of the two pathways. The reentrant focus may excite surrounding tissue at a rate greater than that of the SA node, leading to formation of a clinical tachycardia. The above model is anatomically determined in that there is only one pathway for impulse conduction with a fixed circuit length. Another model of reentry, referred to as a functional reentrant loop or leading circle model, may also occur (Fig. 25–4).[1] In a functional reentrant focus, the length of the circuit may vary depending on the conduction velocity and recovery characteristics of the impulse. The area in the middle of the loop is continually kept refractory by the inwardly moving impulse. The length of the circuit is not fixed but is the smallest circle possible, such that the leading edge of the wavefront is continuously exciting tissue just as it recovers; that is, the head of the impulse nearly catches its tail. It differs from the anatomic model in that the leading edge of the impulse is not preceded by an excitable gap of tissue, and it does not have an obstacle in the middle or a fixed anatomic circuit. Clinically, many reentrant foci probably have both anatomic and functional characteristics. In the figure 8 model, a zone of unidirectional block is present, allowing for two impulse loops that join and reenter the area of block in a retrograde fashion to form a pretzel-shaped reentrant circuit. This model combines functional characteristics with an excitable gap. All of these theoretical models require a critical balance of refractoriness and conduction velocity within the circuit and as such have helped to explain the effects of drugs on terminating, modifying, and causing cardiac rhythm disturbances.

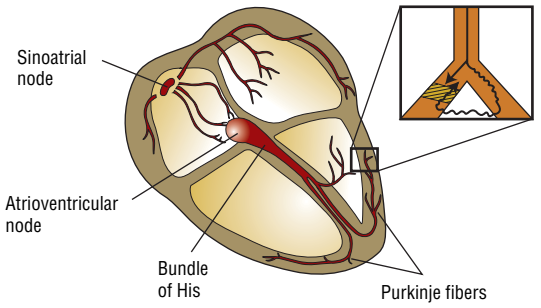

FIGURE 25-3. Conduction system of the heart. The magnified portion shows a bifurcation of a Purkinje fiber traditionally explained as the etiology of reentrant VT. A premature impulse travels to the fiber, damaged by heart disease or ischemia. It encounters a zone of prolonged refractoriness (area of unidirectional block; *cross-hatched area*) but fails to propagate because it remains refractory to stimulation from the previous impulse. However, the impulse may slowly travel *(squiggly line)* through the other portion of the Purkinje twig and will "reenter" the cross-hatched area if the refractory period is concluded and it is now excitable. Thus, the premature impulse never meets refractory tissue; circus movement ensues. If this site stimulates the surrounding ventricle repetitively, clinical reentrant VT results (VT, ventricular tachycardia).

What causes reentry to become clinically manifest? Reentrant foci may occur at any level of the conduction system: within the branches of the specialized atrial conduction system, within the Purkinje network, and even within portions of the SA and AV nodes. The anatomy of the Purkinje system appears to provide a suitable substrate for the formation of microreentrant loops and is often used as a model to facilitate the understanding of reentry concepts (see Fig. 25–4). Of course, because reentry does not usually occur in normal, healthy conduction tissue, various forms of heart disease or conduction abnormalities must usually be present before reentry becomes manifest. In other words, the various forms of heart disease (e.g., coronary artery disease [CAD], LV dysfunction) can result in changes in conduction in the pathways of a suitable reentrant substrate. An often-used example is reentry occurring as a consequence of ischemic or hypoxic damage: with inadequate cellular oxygen, cardiac tissue resorts to anaerobic glycolysis for adenosine triphosphate production. As high-energy phosphate concentration diminishes, the activity of the transmembrane ion pumps declines and RMP rises. This rise in RMP causes inactivation in the voltage-dependent sodium channel, and the tissue begins to assume slow conduction characteristics. If changes in conduction parameters occur in a discordant manner due to varying degrees of ischemia or hypoxia, then a reentry circuit may become manifest. Furthermore, an ischemic, dying cell liberates intracellular potassium, which also causes a rise in RMP. In other cases, reentry may occur as a consequence of anatomic or functional variants in the normal conduction system. For instance, patients may possess two (instead of one) conduction pathways near or within the AV node, or have an anomalous extranodal AV pathway that possesses different electrophysiologic characteristics from the normal AV nodal pathway. Reentry in these cases may occur within the AV node or encompass both atrial and ventricular tissue. Reentrant tachycardias have the

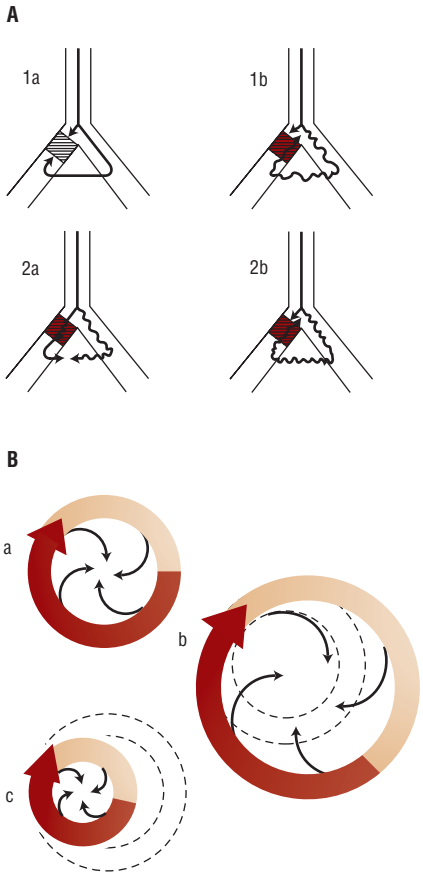

FIGURE 25-4. *A.* Possible mechanism of proarrhythmia in the anatomic model of reentry. *(1a)* Nonviable reentrant loop due to bidirectional block *(shaded area)*. *(1b)* Instance where a drug slows conduction velocity without significantly prolonging the refractory period. The impulse is now able to reenter the area of unidirectional block *(shaded area)* because slowed conduction through the contralateral limb allows recovery of the block. A new reentrant tachycardia may result. *(2a)* Nonviable reentrant loop due to a lack of a unidirectional block. *(2b)* Instance where a drug prolongs the refractory period without significantly slowing conduction velocity. The impulse moving antegrade meets refractory tissue *(shaded area)* allowing for unidirectional block. A new reentrant tachycardia may result. *B.* Mechanism of reentry and proarrhythmia. *(a)* Functionally determined *(leading circle)* reentrant circuit. This model should be contrasted with anatomic reentry; here the circuit is not fixed (it does not necessarily move around an anatomic obstacle) and there is no excitable gap. All tissue inside is held continuously refractory. *(b)* Instance where a drug prolongs the refractory period without significantly slowing conduction velocity. The tachycardia may terminate or slow in rate as shown as a consequence of a greater circuit length. The *dashed lines* represent the original reentrant circuit prior to drug treatment. *(c)* Instance where a drug slows conduction velocity without significantly prolonging the refractory period (i.e., class Ic antiarrhythmic drugs) and accelerates the tachycardia. The tachycardia rate may increase (proarrhythmia) as shown as a consequence of a shorter circuit length. The dashed lines represent the original reentrant circuit prior to drug treatment. *(From McCollam PL, Parker RB, Beckman KJ, et al. Proarrhythmia: A paradoxic response to antiarrhythmic agents. Pharmacotherapy 1989;9:146, with permission.)*

following characteristics: (a) the onset of the tachycardia is usually related to an initiating event (i.e., premature beat); (b) the initiating beat is usually different in morphology from subsequent beats of the tachycardia; (c) the initiation of the tachycardia is usually possible with programmed cardiac stimulation; and (d) the initiation and termination of the tachycardia is usually abrupt without an acceleration or deceleration phase. There are many examples of reentrant tachycardias, including AF, atrial flutter, AV nodal or AV reentrant tachycardia, and recurrent VT.

ANTIARRHYTHMIC DRUGS

In a theoretical sense, drugs may have antiarrhythmic activity by directly altering conduction in several ways. First, a drug may depress the automatic properties of abnormal pacemaker cells. A drug may do this by decreasing the slope of phase 4 depolarization and/or by elevating threshold potential. If the rate of spontaneous impulse generation of the abnormally automatic foci becomes less than that of the SA node, normal cardiac rhythm can be restored. Second, drugs may alter the conduction characteristics of the pathways of a reentrant loop.[1,2] A drug may facilitate conduction (shorten refractoriness) in the area of unidirectional block, allowing antegrade conduction to proceed. On the other hand, a drug may further depress conduction (prolong refractoriness) either in the area of unidirectional block or in the pathway with slowed conduction and a relatively shorter refractory period. If refractoriness is prolonged in the area of unidirectional block, retrograde propagation of the impulse is not permitted, causing a "bidirectional" block. In the anatomic model, if refractoriness is prolonged in the pathway with slow conduction, antegrade conduction of the impulse is not permitted. In either case, drugs that reduce the discordance and cause uniformity in conduction properties of the two pathways may suppress the reentrant substrate. In the functionally determined model, if refractoriness is prolonged without significantly slowing conduction velocity, the tachycardia may terminate or slow in rate as a consequence of a greater circuit length (see Fig. 25–4). There are other theoretical ways to stop reentry: a drug may eliminate the critically timed premature impulse that triggers reentry; a drug may slow conduction velocity to such an extent that conduction is extinguished; or a drug may reverse the underlying form of heart disease that was responsible for the conduction abnormalities that led to the arrhythmia (i.e., "reverse remodeling").

AADs have specific electrophysiologic actions that alter cardiac conduction in patients with or without heart disease. These actions form the basis of grouping AADs into specific categories based upon their electrophysiologic actions *in vitro*. Vaughan Williams proposed the most frequently used classification system (Table 25–1).[2] This classification has been criticized for the following reasons: (a) it is incomplete and does not allow for the classification of drugs such as digoxin or adenosine; (b) it is not pure, and many agents have properties of more than one class of drugs; (c) it does not incorporate drug characteristics such as mechanisms of tachycardia termination/prevention, clinical indications, or side effects; and (d) drugs become "labeled" within a class, although they may be distinct in many regards.[3] These criticisms formed the basis for an attempt to reclassify AADs based upon a variety of basic and clinical characteristics (called the Sicilian Gambit[3]). Nonetheless, the Vaughan Williams classification remains the most frequently used despite many proposed modifications and alternative systems.

The class Ia AADs, quinidine, procainamide, and disopyramide, slow conduction velocity, prolong refractoriness, and decrease the automatic properties of sodium-dependent (normal and diseased) conduction tissue. Although class Ia AADs are primarily considered sodium channel blockers, their electrophysiologic actions can also be attributed to blockade of potassium channels. In reentrant tachycardias, these drugs generally depress conduction and prolong refractoriness, theoretically transforming the area of unidirectional block into a bidirectional block. Clinically, class Ia drugs are broad-spectrum AADs that are effective for both supraventricular and ventricular arrhythmias. Procainamide is only available in the IV formulation as all of its oral formulations have been discontinued.

The class Ib AADs, lidocaine, mexiletine, and phenytoin, were historically categorized separately from quinidine-like drugs. This was a result of early work demonstrating that lidocaine had distinctly different electrophysiologic actions. In normal tissue models,

TABLE 25-1 Classification of Antiarrhythmic Drugs

Class	Drug	Conduction Velocity[a]	Refractory Period	Automaticity	Ion Block
Ia	Quinidine Procainamide Disopyramide	↓	↑	↓	Sodium (intermediate) Potassium
Ib	Lidocaine Mexiletine	0/↓	↓	↓	Sodium (fast on-off)
Ic	Flecainide Propafenone[b]	↓↓	0	↓	Sodium (slow on-off)
II[c]	β-blockers	↓	↑	↓	Calcium (indirect)
III	Amiodarone[d] Dofetilide Dronedarone[d] Sotalol[b] Ibutilide	0	↑↑	0	Potassium
IV[c]	Verapamil Diltiazem	↓	↑	↓	Calcium

AV, atrioventricular; SA, sinoatrial.
[a]Variables for normal tissue models in ventricular tissue.
[b]Also has β-blocking actions.
[c]Variables for SA and AV nodal tissue only.
[d]Also has sodium, calcium, and β-blocking actions; see Table 25–2 (for amiodarone).

lidocaine generally facilitates actions on cardiac conduction by shortening refractoriness and having little effect on conduction velocity. Thus, it was postulated that these agents could improve antegrade conduction, eliminating the area of unidirectional block. Of course, arrhythmias do not usually arise from normal tissue, leading investigators to study the actions of lidocaine and phenytoin in ischemic and hypoxic tissue models. Interestingly, studies have shown these drugs to possess class Ia quinidine-like properties in diseased tissues. Therefore, it is probable that lidocaine acts in a similar fashion to the class Ia AADs (i.e., prolong refractoriness in diseased ischemic tissues leading to bidirectional block in a reentrant circuit). Lidocaine and similar agents have accentuated effects in ischemic tissue caused by the local acidosis and potassium shifts that occur during cellular hypoxia. Changes in pH alter the time that local anesthetics occupy the sodium channel receptor, thereby affecting the agent's electrophysiologic actions. In addition, the intracellular acidosis that ensues as a consequence of ischemia could cause lidocaine to become "trapped" within the cell, allowing increased access to the receptor. The class Ib AADs are considerably more effective in ventricular arrhythmias than supraventricular arrhythmias. As a group these drugs are relatively weak sodium channel antagonists (at normal stimulation rates).

The class Ic AADs, propafenone and flecainide, are extremely potent sodium channel blockers, profoundly slowing conduction velocity while leaving refractoriness relatively unaltered. The class Ic AADs theoretically eliminate reentry by slowing conduction to a point where the impulse is extinguished and cannot propagate further. Although the class Ic AADs are effective for both ventricular and supraventricular arrhythmias, their use for ventricular arrhythmias has been limited by the risk of proarrhythmia.

Class I AADs are grouped together because of their common action in blocking sodium conductance. The receptor site for these AADs is probably inside the sodium channel so that, in effect, the drug plugs the pore. The agent may gain access to the receptor either via the intracellular space through the membrane lipid bilayer or directly through the channel. Several principles are inherent in antiarrhythmic sodium channel receptor theories:[4]

1. Class I AADs have predominant affinity for a particular state of the channel (e.g., during activation or inactivation). For example, lidocaine and flecainide block sodium current primarily when the cell is in the inactivated state, whereas quinidine is predominantly an open (or activated)-channel blocker.
2. Class I AADs have specific binding and unbinding characteristics to the receptor. For example, lidocaine binds to and dissociates from the channel receptor quickly ("fast on-off") but flecainide has very "slow on-off" properties. This explains why flecainide has such potent effects on slowing ventricular conduction, whereas lidocaine has little effect on normal tissue (at normal heart rates). In general, the class Ic AADs are "slow on-off", the class Ib AADs are "fast on-off", and the class Ia AADs are intermediate in their binding kinetics.
3. Class I AADs possess rate dependence (i.e., sodium channel blockade and slowed conduction are greatest at fast heart rates and least during bradycardia). For "slow on-off" drugs, sodium channel blockade is evident at normal rates (60 to 100 beats/min) but for "fast on-off" agents, slowed conduction is only apparent at fast heart rates.
4. Class I AADs (except phenytoin) are weak bases with a pK_a>7.0 and block the sodium channel in their ionized form. Consequently, pH will alter these actions: acidosis accentuates and alkalosis diminishes sodium channel blockade.
5. Class I AADs appear to share a single receptor site in the sodium channel. It should be noted, however, that a number of class I AADs have other electrophysiologic properties. For instance, quinidine has potent potassium channel blocking activity (manifest predominantly at low concentrations) as does *N*-acetylprocainamide (manifest predominantly at high concentrations), the primary metabolite of procainamide. Additionally propafenone has β-blocking actions.

These principles are important in understanding additive drug combinations (e.g., quinidine and mexiletine), antagonistic combinations (e.g., flecainide and lidocaine), and potential antidotes to excess sodium channel blockade (sodium bicarbonate). They also explain a number of clinical observations, such as why lidocaine-like drugs are relatively ineffective for supraventricular tachycardia. The class Ib AADs are "fast on-off", inactivated sodium

channel blockers; atrial cells, however, have a very brief inactivated phase relative to ventricular tissue.

The β-blockers are classified as class II AADs. For the most part, the clinically relevant acute antiarrhythmic mechanisms of the β-blockers result from their antiadrenergic actions. Because the SA and AV nodes are heavily influenced by adrenergic innervation, β-blockers would be most useful in tachycardias in which these nodal tissues are abnormally automatic or are a portion of a reentrant loop. These drugs are also helpful in slowing ventricular response in atrial arrhythmias (e.g., AF) by their effects on the AV node. Furthermore, some tachycardias are exercise-related or precipitated by states of high sympathetic tone (perhaps through triggered activity), and β-blockers may be useful in these instances. β-adrenergic stimulation results in increased conduction velocity, shortened refractoriness, and increased automaticity of the nodal tissues; β-blockers will antagonize these effects. In the nodal tissues, β-blockers interfere with calcium entry into the cell by altering catecholamine-dependent channel integrity and gating kinetics. In sodium-dependent atrial and ventricular tissue, β-blockers shorten repolarization somewhat but otherwise have little direct effect. The antiarrhythmic properties of β-blockers observed with long-term, chronic therapy in patients with heart disease are less well understood. Although it is clear that β-blockers decrease the likelihood of SCD (presumably arrhythmic death) after MI, the mechanism for this benefit remains unclear but may relate to the complex interplay of changes in sympathetic tone, damaged myocardium, and ventricular conduction. In patients with HF, drugs such as β-blockers, angiotensin-converting enzyme inhibitors, and angiotensin II receptor blockers may prevent arrhythmias such as AF by attenuating the structural and/or electrical remodeling process in the myocardium.[5,6]

The class III AADs include those agents that specifically prolong refractoriness in atrial and ventricular tissue. This class includes very different drugs: amiodarone, dronedarone, sotalol, ibutilide, and dofetilide; they share the common effect of delaying repolarization by blocking potassium channels. Amiodarone and sotalol are effective in most supraventricular and ventricular arrhythmias. Amiodarone displays electrophysiologic characteristics of all four Vaughan Williams classes; it is a sodium channel blocker with relatively "fast on-off" kinetics, has nonselective β-blocking actions, blocks potassium channels, and also has a small degree of calcium channel blocking activity (Table 25–2). At normal heart rates and with chronic use, its predominant effect is to prolong repolarization. Upon IV administration, its onset is relatively quick (unlike the oral form) and β-blockade predominates initially. Theoretically, amiodarone, like class I AADs, may interrupt the reentrant substrate by transforming an area of unidirectional block into an area of bidirectional block. However, electrophysiologic studies using programmed cardiac stimulation imply that amiodarone may leave the reentrant loop intact. The impressive effectiveness of amiodarone coupled with its low proarrhythmic potential has challenged the notion that selective ion channel blockade by AADs is preferable. Sotalol is a potent inhibitor of outward potassium movement during repolarization and also possesses nonselective β-blocking actions. Unlike amiodarone and sotalol, dronedarone, ibutilide and dofetilide are only approved for the treatment of supraventricular arrhythmias. Both ibutilide (only available IV) and dofetilide (only available orally) can be used for the acute conversion of AF or atrial flutter to SR. Dofetilide can also be used to maintain SR in patients with AF or atrial flutter of longer than 1 week's duration who have been converted to SR. Dronedarone is approved to reduce the risk of cardiovascular hospitalization in patients with paroxysmal or persistent AF or atrial flutter who experienced a recent episode of this arrhythmia, have cardiovascular risk factors (at least 70 years of age, hypertension, diabetes, prior stroke, left atrial diameter ≥50 mm, or left ventricular ejection fraction [LVEF] <40%), and are in or will be cardioverted to SR. Although structurally related to amiodarone, dronedarone's structure has been modified through the addition of a methylsulfonyl group and the removal of iodine. Dronedarone is also similar to amiodarone in exhibiting electrophysiologic characteristics of all four Vaughan Williams classes (sodium channel blocker with relatively "fast on-off" kinetics, nonselective β-blocker, potassium channel blocker, and calcium channel antagonist).

There are a number of different potassium channels that function during normal conduction; all approved class III AADs inhibit the delayed rectifier current (I_K) responsible for phases 2 and 3 repolarization. Subcurrents make up I_K; an ultrarapid component (I_{Kur}), a rapid component (I_{Kr}), and the slow component (I_{Ks}). *N*-acetylprocainamide, sotalol, ibutilide, and dofetilide selectively block I_{Kr}, whereas amiodarone and dronedarone block both I_{Kr} and I_{Ks}. New drugs that selectively block I_{Kur} (found predominantly in the atrium but not ventricle) are being investigated for supraventricular arrhythmias. The clinical relevance of selectively blocking components of the delayed rectifier current remains to be determined. Potassium channel blockers (particularly those with selective I_{Kr} blocking properties) display "reverse use dependence" (i.e., their effects on repolarization are greatest at low heart rates). Sotalol and drugs like it also appear to be much more effective in preventing VF (in dog models) than the traditional sodium channel blockers. They also decrease defibrillation threshold in contrast to class I AADs, which tend to increase this parameter. This feature could be important in patients with ICDs, as concurrent therapy with class I AADs may require more energy for successful cardioversion or may render the ICD ineffective in terminating the ventricular arrhythmia. The Achilles' heel of all class III AADs is an extension of their underlying ionic mechanism (i.e., by blocking potassium channels and delaying repolarization, they may also cause proarrhythmia in the form of TdP by provoking EADs).

The non-DHP CCBs, verapamil and diltiazem, are categorized as class IV AADs. At least two types of calcium channels are operative

TABLE 25-2 Time Course and Electrophysiologic Effects of Amiodarone

				IV		Oral	
Class	**Mechanism**	**EP**	**ECG**	***Minutes–Hours***	***Hours–Days***	***Days–Weeks***	***Weeks–Months***
Class I	Na^+ block	↑ HV	↑ QRS	0	+	+	++
Class II	β-block	↑ AH	↑ PR ↓ HR	++	++	++	++
Class III	K^+ block	↑ VERP ↑ AERP	↑ QT	0	+	++	++++
Class IV	Ca^{2+} block[a]	↑ AH	↑ PR	+	+	+	+

[a]Rate-dependent.

in SA and AV nodal tissues: an L-type channel and a T-type channel. Both L-type channel blockers (verapamil and diltiazem) and selective T-type channel blockers (mibefradil was previously approved but withdrawn from the market) will slow conduction, prolong refractoriness, and decrease automaticity (e.g., due to EADs or LADs) of the calcium-dependent tissue in the SA and AV nodes. Therefore, these agents are effective in automatic or reentrant tachycardias, which arise from or use the SA or AV nodes. In supraventricular arrhythmias (e.g., AF), these drugs can slow ventricular response by slowing AV nodal conduction. Furthermore, because calcium entry seems to be integral to exercise-related tachycardias and/or tachycardias caused by some forms of triggered automaticity, these agents may be effective in the treatment of these types of arrhythmias. The DHP CCBs (e.g., nifedipine) do not have significant antiarrhythmic activity because a reflex increase in sympathetic tone caused by vasodilation counteracts their direct negative dromotropic action.

All AADs currently available have an impressive side effect profile (Table 25–3). A considerable percentage of patients cannot tolerate long-term therapy with these drugs and will have to discontinue therapy because of side effects. 2 In one trial,[7] more than 50% of patients had to discontinue long-term procainamide (mostly because of a lupus-like syndrome) after MI. In another study,[8] disopyramide caused anticholinergic side effects in approximately 70% of patients. Flecainide, propafenone, and disopyramide may precipitate congestive HF in a significant number of patients with underlying LV systolic dysfunction; consequently, these drugs should be avoided in this patient population.[9] The class Ib AAD, mexiletine, causes neurologic and/or gastrointestinal toxicity in a high percentage of patients. One of the most frightening side effects related to AADs is the aggravation of underlying ventricular arrhythmias or the precipitation of new (and life-threatening) ventricular arrhythmias.[10]

TABLE 25-3 Side Effects of Antiarrhythmic Drugs

Disopyramide	Anticholinergic symptoms (dry mouth, urinary retention, constipation, blurred vision), nausea, anorexia, TdP, HF, conduction disturbances, ventricular arrhythmias
Procainamide[a]	Hypotension, TdP, worsening HF, conduction disturbances, ventricular arrhythmias
Quinidine	Cinchonism, diarrhea, abdominal cramps, nausea, vomiting, hypotension, TdP, worsening HF, conduction disturbances, ventricular arrhythmias, fever, hepatitis, thrombocytopenia, hemolytic anemia
Lidocaine	Dizziness, sedation, slurred speech, blurred vision, paresthesia, muscle twitching, confusion, nausea, vomiting, seizures, psychosis, sinus arrest, conduction disturbances
Mexiletine	Dizziness, sedation, anxiety, confusion, paresthesia, tremor, ataxia, blurred vision, nausea, vomiting, anorexia, conduction disturbances, ventricular arrhythmias
Flecainide	Blurred vision, dizziness, dyspnea, headache, tremor, nausea, worsening HF, conduction disturbances, ventricular arrhythmias
Propafenone	Dizziness, fatigue, bronchospasm, headache, taste disturbances, nausea, vomiting, bradycardia or AV block, worsening HF, ventricular arrhythmias
Amiodarone	Tremor, ataxia, paresthesia, insomnia, corneal microdeposits, optic neuropathy/neuritis, nausea, vomiting, anorexia, constipation, TdP (<1%), bradycardia or AV block (IV and oral use), pulmonary fibrosis, liver function test abnormalities, hepatitis, hypothyroidism, hyperthyroidism, photosensitivity, blue-gray skin discoloration, hypotension (IV use), phlebitis (IV use)
Dofetilide	Headache, dizziness, TdP
Dronedarone	Nausea, vomiting, diarrhea, serum creatinine elevations, bradycardia, TdP (<1%)
Ibutilide	Headache, TdP, hypotension
Sotalol	Dizziness, weakness, fatigue, nausea, vomiting, diarrhea, bradycardia or AV block, TdP, bronchospasm, worsening HF

[a]Side effects listed are for the IV formulation only; oral formulations are no longer available.
AV, atrioventricular; HF, heart failure; IV, intravenous; TdP, torsade de pointes.

Amiodarone has assumed a prominent place in the treatment of both chronic and acute supraventricular and ventricular arrhythmias and is now the most commonly prescribed AAD.[11] Once considered a drug of last resort, it is now the first AAD considered in many arrhythmias. Yet amiodarone is a peculiar and complex drug, displaying unusual pharmacologic effects, pharmacokinetics, dosing regimens, and multiorgan side effects. Amiodarone has an extremely long elimination half-life (greater than 50 days) and large volume of distribution; consequently, its onset of action with the oral form is delayed (days to weeks) despite the use of a loading regimen, and its effects persist for a long period (months) after discontinuation. Amiodarone is a substrate of the cytochrome P450 (CYP) 3A4 isoenzyme, a moderate inhibitor of many CYP isoenzymes (e.g., CYP2C9, CYP2D6, CYP3A4), and a P-glycoprotein inhibitor, all of which can result in the potential for numerous drug interactions. Amiodarone interacts with digoxin and warfarin and can significantly increase plasma concentrations of both drugs. By inhibiting P-glycoprotein, amiodarone can increase digoxin concentrations by approximately twofold; therefore, the digoxin dose should be empirically reduced by 50% when amiodarone is initiated. When amiodarone and warfarin are initiated concurrently, warfarin should be started at a dose of 2.5 mg daily. When amiodarone is initiated in a patient already receiving warfarin, the warfarin dose should be reduced by approximately 30%.[12] Acute administration of amiodarone is usually well tolerated by patients, but severe organ toxicities may result with chronic use. Severe bradycardia (sometimes requiring pacing to allow the patient to remain on amiodarone), hyper- and hypothyroidism, peripheral neuropathy, gastrointestinal discomfort, photosensitivity, and a blue-gray skin discoloration on exposed areas are common. Fulminant hepatitis (uncommon) and pulmonary fibrosis (5% to 10% of patients) have caused death.[13,14] Although amiodarone can cause corneal microdeposits (which usually do not affect vision) in virtually every patient, it has also been associated with the development of optic neuropathy/neuritis, which can lead to blindness. All of these side effects mandate close and continued monitoring (liver enzymes, thyroid function tests, eye exams, chest radiographs, pulmonary function tests) and have led to a proliferation of "amiodarone clinics" designed just for patients receiving this drug on a chronic basis (Table 25–4). 3[15]

The modifications to dronedarone's chemical structure may confer an improved safety profile when compared with amiodarone. With the addition of a methylsulfonyl group and the deletion of the iodine moiety, dronedarone is less lipophilic than amiodarone; consequently, dronedarone is much less likely to accumulate in tissues and to cause various organ toxicities. Dronedarone also has a considerably shorter half-life (~24 hours) when compared with amiodarone, which allows for steady-state to be achieved in 5 to 7 days, without the need for using loading doses. Like amiodarone, dronedarone is a substrate of the CYP3A isoenzyme and a moderate inhibitor of the CYP2D6 and CYP3A isoenzymes. Its use with potent CYP3A4 inhibitors or inducers should be avoided. No significant interaction has been observed when dronedarone was used concomitantly with warfarin. Dronedarone also inhibits P-glycoprotein and can increase digoxin concentrations by about 2.5-fold. Consequently, when concomitantly using dronedarone and digoxin, the digoxin dose should be empirically reduced by 50%.

Table 25–5 summarizes the pharmacokinetics of the AADs and Table 25–6 lists recommended dosages of the oral dosage forms. Table 25–7 lists the dosing recommendations for the IV forms of various AADs.

TABLE 25-4 Amiodarone Monitoring

Side Effect	Monitoring Recommendations	Management of Side Effect
Pulmonary fibrosis	Chest radiograph (baseline, then every 12 months) Pulmonary function tests (if symptoms develop)	Discontinue amiodarone immediately; initiate corticosteroid therapy
Hypothyroidism	TFTs (baseline, then every 6 months)	Thyroid hormone supplementation (e.g., levothyroxine)
Hyperthyroidism	TFTs (baseline, then every 6 months)	Antithyroid drugs (e.g., methimazole)
Optic neuritis/neuropathy	Ophthalmologic examination (baseline [only if significant visual abnormalities present], then if symptoms develop)	Discontinue amiodarone immediately
Corneal microdeposits	Slit-lamp examination (routine monitoring not necessary)	No treatment necessary
Hepatotoxicity	LFTs (baseline, then every 6 months)	Lower the dose or discontinue amiodarone if LFTs >3× the upper limit of normal
Bradycardia/heart block	ECG (baseline, then every 3 to 6 months)	Lower the dose, if possible, or discontinue amiodarone if severe
Tremor, ataxia, peripheral neuropathy	History/physical examination (each office visit)	Lower the dose, if possible, or discontinue amiodarone if severe
Photosensitivity/blue-gray skin discoloration	History/physical examination (each office visit)	Advise patients to wear sunblock while outdoors

ECG, electrocardiogram; LFTs, liver function tests, TFTs, thyroid function tests.

TABLE 25-5 Pharmacokinetics of Antiarrhythmic Drugs

Drug	Oral Bioavailability (%)	Primary Route of Elimination[a]	Substrate[b]	Inhibitor[b]	V_{Dss} (L/kg)	Protein Binding (%)	$t_{1/2}$[c]	Therapeutic Range (mg/L)
Disopyramide	70–95	H/R	CYP3A4 (M)	–	0.8–2.0	50–80	4–8 h	2–6
Procainamide	75–95	H/R	NAT CYP2D6 (M)	–	1.5–3.0	10–20	5–6 h (SAs) 2–3 h (FAs)	4–15
Quinidine	70–80	H	CYP3A4 (M) CYP2C9	CYP2D6 (S) CYP3A4 (S) CYP2C9 P-GP	2.0–3.5	80–90	5–9 h	2–6

[a]H, hepatic; R, renal.
[b]CYP, cytochrome P450 isoenzyme; M, major; NAT, *N*-acetyltransferase; P-GP, P-glycoprotein; S, strong.
[c]EMs, extensive metabolizers; FAs, fast acetylators; PMs, poor metabolizers; SAs, slow acetylators.
[d]Variables for parent compound (not 5-OH-propafenone).

TABLE 25-6 Typical Maintenance Doses of Oral Antiarrhythmic Drugs

Drug	Dose	Dose Adjusted
Disopyramide	100–150 mg q 6 h 200–300 mg q 12 h (SR form)	HEP, REN
Quinidine	200–300 mg sulfate salt q 6 h 324–648 gluconate salt q 8–12 h	HEP
Mexiletine	200–300 mg q 8 h	HEP
Flecainide	50–200 mg q 12 h	HEP, REN
Propafenone	150–300 mg q 8 h 225-425 mg q 12 h (SR form)	HEP
Amiodarone	400 mg two to three times daily until 10 g total, then 200–400 mg daily[a]	
Dofetilide	500 mcg q 12 h	REN[b]
Dronedarone	400 mg twice daily (with meals)[c]	
Sotalol	80–160 mg q 12 h	REN[d]

HEP, hepatic disease; REN, renal dysfunction; SR, sustained release.
[a]Usual maintenance dose for atrial fibrillation is 200 mg/day (may further decrease dose to 100 mg/day with long-term use if patient clinically stable in order to decrease risk of toxicity); usual maintenance dose for ventricular arrhythmias is 300–400 mg/day.
[b]Dose should be based upon creatinine clearance; should not be used when creatinine clearance <20 mL/min.
[c]Should not be used in severe hepatic impairment.
[d]Should not be used for atrial fibrillation when creatinine clearance <40 mL/min.

TABLE 25-7 Intravenous Antiarrhythmic Dosing

Drug	Clinical Situation	Dose
Amiodarone	Pulseless VT/VF	300 mg IV/IO push (can give additional 150 mg IV/IO push if persistent VT/VF), followed by infusion of 1 mg/min for 6 h, then 0.5 mg/min
	Stable VT (with a pulse)	150 mg IV over 10 min, followed by infusion of 1 mg/min for 6 h, then 0.5 mg/min
	AF (termination)	5 mg/kg IV over 30 min, followed by infusion of 1 mg/min for 6 h, then 0.5 mg/min
Diltiazem	PSVT; AF (rate control)	0.25 mg/kg IV over 2 min (may repeat with 0.35 mg/kg IV over 2 min), followed by infusion of 5–15 mg/h
Ibutilide	AF (termination)	1 mg IV over 10 min (may repeat if needed)
Lidocaine	Pulseless VT/VF	1–1.5 mg/kg IV/IO push (can give additional 0.5–0.75 mg/kg IV/IO push every 5–10 min if persistent VT/VF [maximum cumulative dose = 3 mg/kg]), followed by infusion of 1–4 mg/min (1–2 mg/min if liver disease or HF)
	Stable VT (with a pulse)	1–1.5 mg/kg IV push (can give additional 0.5–0.75 mg/kg IV push every 5–10 min if persistent VT [maximum cumulative dose = 3 mg/kg]), followed by infusion of 1–4 mg/min (1–2 mg/min if liver disease or HF)
Procainamide	AF (termination); stable VT (with a pulse)	15–18 mg/kg IV over 60 min, followed by infusion of 1–4 mg/min
Sotalol[a]	AF/AFl (SR maintenance) Ventricular arrhythmias	75–150 mg IV once or twice daily (infused over 5 h)[b]
Verapamil	PSVT; AF (rate control)	2.5–5 mg IV over 2 min (may repeat up to maximum cumulative dose of 20 mg); can follow with infusion of 2.5–10 mg/h

AF, atrial fibrillation; AFl, atrial flutter; HF, heart failure; IO, intraosseous; IV, intravenous; PSVT, paroxysmal supraventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia.
[a]Should be used only when patients are unable to take sotalol orally.
[b]IV sotalol should be administered at the same frequency as oral sotalol (based on creatinine clearance). Oral sotalol may be converted to IV sotalol as follows: 80 mg oral = 75 mg IV; 120 mg oral = 112.5 mg IV; 160 mg oral = 150 mg IV.

SUPRAVENTRICULAR ARRHYTHMIAS

The common supraventricular tachycardias that often require drug treatment are (a) AF or atrial flutter; (b) PSVT; and (c) automatic atrial tachycardias. Other common supraventricular arrhythmias that usually do not require drug therapy include premature atrial complexes, wandering atrial pacemaker, sinus arrhythmia, and sinus tachycardia. As an example, premature atrial complexes rarely cause symptoms, never cause hemodynamic compromise, and therefore drug therapy is usually not indicated. Likewise, sinus tachycardia is usually the result of underlying metabolic or hemodynamic disorders (e.g., infection, dehydration, hypotension), and therapy should be directed at the underlying cause, not the tachycardia per se. Of course, there are exceptions to these suggestions. For example, sinus tachycardia may be deleterious in patients after cardiac surgery or MI. Therefore, AADs, such as β-blockers, may be indicated in these situations. Stated in another way, although many arrhythmias generally do not require therapy, clinical judgment and patient-specific variables play an important role in this decision. Nevertheless, for the purpose of this discussion, only the tachycardias usually requiring AAD therapy, as listed earlier, are addressed.

ATRIAL FIBRILLATION AND ATRIAL FLUTTER

Mechanisms and Background

AF and atrial flutter are common supraventricular tachycardias. AF continues to be the most common sustained arrhythmia encountered in clinical practice, affecting approximately 2.2 million Americans.[16] In the general population, the overall prevalence of AF is 0.4% to 1%, and this increases with age (e.g., approximately an 8% prevalence in patients >80 years old).[17] The prevalence of AF also appears to increase as patients develop more severe HF, increasing from 4% in asymptomatic NYHA class I patients to 50% in patients with NYHA class IV HF.[17] With the aging population; improved survival in patients with HF, CAD, and hypertension; and the increased frequency of surgical procedures being performed, it is expected that the prevalence of AF will dramatically increase to an estimated 12 to 15 million by the year 2050.[18] Based on data derived from the Framingham study cohort, the general lifetime risk for AF in men and women at least 40 years of age is estimated to be 1 in 4.[19]

AF and atrial flutter may present as a chronic, established tachycardia; an acute tachycardia; or a self-terminating, paroxysmal form. The following semantics and definitions are sometimes used specifically for AF:[17,20] acute AF (onset within 48 hours); paroxysmal AF (terminates spontaneously in <7 days); recurrent AF (two or more episodes); persistent AF (duration >7 days and does not terminate spontaneously); and permanent AF (does not terminate with attempts at pharmacologic or electrical cardioversion). AF is characterized by extremely rapid (atrial rate of 400 to 600 beats/min) and disorganized atrial activation. With this disorganized atrial activity, there is a loss of the contribution of synchronized atrial contraction (atrial kick) to forward cardiac output. Supraventricular impulses penetrate the AV conduction system in

CLINICAL PRESENTATION: SUPRAVENTRICULAR TACHYCARDIAS

Atrial Fibrillation/Flutter

General

- These rhythms are usually not directly life threatening and do not generally cause hemodynamic collapse or syncope; 1:1 atrial flutter (ventricular response ~300 beats/min) is an exception. Also, patients with underlying forms of heart disease that are heavily reliant on atrial contraction to maintain adequate cardiac output (e.g., mitral stenosis, obstructive cardiomyopathy) display more severe symptoms of AF or atrial flutter.

Symptoms

- Most often, patients complain of rapid heart rate/palpitations and/or worsening symptoms of HF (shortness of breath, fatigue). Medical emergencies are severe HF (i.e., pulmonary edema, hypotension) or AF occurring in the setting of acute MI.

Diagnostic Tests/Signs (ECG; See Text for Details)

- AF is an irregularly irregular supraventricular rhythm with no discernible, consistent atrial activity (P waves). Ventricular response is usually 120 to 180 beats/min and the pulse is irregular. Atrial flutter is (usually) a regular supraventricular rhythm with characteristic flutter waves (or sawtooth pattern) reflecting more organized atrial activity. Commonly, the ventricular rate is in factors of 300 beats/min (e.g., 150, 100, or 75 beats/min).

Paroxysmal Supraventricular Tachycardia Caused by Reentry

General

- These rhythms can be transient, resulting in little, if any, symptoms.

Symptoms

- Patients frequently complain of intermittent episodes of rapid heart rate/palpitations that abruptly start and stop, usually without provocation (but occasionally as a result of exercise). Severe symptoms include syncope. Often (in particular, those with AV nodal reentry), patients complain of a chest pressure or neck sensation. This is caused by simultaneous AV contraction with the right atrium contracting against a closed tricuspid valve. Life-threatening symptoms (syncope, hemodynamic collapse) are associated with an extremely rapid heart rate (e.g., >200 beats/min) and AF associated with an accessory AV pathway.

Diagnostic Tests/Signs (ECG; See Text for Details)

- Most commonly, PSVT is a rapid, narrow QRS tachycardia (regular in rhythm) that starts and stops abruptly. Atrial activity, although present, is difficult to ascertain on surface ECG because P waves are "buried" on the QRS or T wave.

variable degrees resulting in an irregular activation of the ventricles and an irregularly, irregular pulse. The AV junction will not conduct most of the supraventricular impulses, causing ventricular response to be considerably slower (120 to 180 beats/min) than the atrial rate. It is sometimes stated that "AF begets AF"; that is, the arrhythmia tends to perpetuate itself. Long episodes are more difficult to terminate perhaps because of tachycardia-induced changes in atrial function (mechanical and/or electrical "remodeling").

Atrial flutter occurs less frequently than AF but is similar in its precipitating factors, consequences, and drug therapy approach. This arrhythmia is characterized by rapid (270 to 330 atrial beats/min) but regular atrial activation. The slower and regular electrical activity results in a regular ventricular response that is in approximate factors of 300 beats/min (i.e., 1:1 AV conduction = ventricular rate of 300 beats/min; 2:1 AV conduction = ventricular rate of 150 beats/min; 3:1 AV conduction = ventricular rate of 100 beats/min). Atrial flutter may occur in two distinct forms (type I and type II). Type I flutter is the more common classic form with atrial rates of approximately 300 beats/min and the typical "sawtooth" pattern of atrial activation as shown by the surface ECG. Type II flutter tends to be faster, being somewhat of a hybrid between classic atrial flutter and AF. Although the ventricular response usually has a regular pattern, atrial flutter with varying degrees of AV block or that occur with episodes of AF ("fib-flutter") can cause an irregular ventricular rate.

It is generally accepted that the predominant mechanism of AF and atrial flutter is reentry. AF appears to result from multiple atrial reentrant loops (or wavelets), whereas atrial flutter is caused by a single, dominant, reentrant substrate (counterclockwise circus movement in the right atrium around the tricuspid annulus). AF or atrial flutter usually occurs in association with various forms of structural heart disease (SHD) that cause atrial distension, including myocardial ischemia or infarction, hypertensive heart disease, valvular disorders such as mitral stenosis or mitral insufficiency, congenital abnormalities such as septal defects, dilated or hypertrophic cardiomyopathy, and obesity. Disorders that cause right atrial stretch and are associated with AF or atrial flutter include acute pulmonary embolus and chronic lung disease resulting in pulmonary hypertension and cor pulmonale. AF may also occur in association with states of high adrenergic tone such as thyrotoxicosis, surgery, alcohol withdrawal, sepsis, and excessive physical exertion. AF that develops in the absence of clinical, electrocardiographic, radiographic, and echocardiographic evidence of SHD is defined as lone AF. Other states in which patients are predisposed to episodes of AF are the presence of an anomalous AV pathway (i.e., Kent bundle) and sinus node dysfunction (i.e., sick sinus syndrome).

Patients with AF or atrial flutter may experience the entire range of symptoms associated with other supraventricular tachycardias, although syncope as a presenting symptom is uncommon. Because atrial kick is lost with the onset of AF, patients with LV systolic or diastolic dysfunction may develop worsening signs and symptoms of HF as they often depend on the contribution of their atrial kick to maintain an adequate cardiac output. Thromboembolic events, resulting from atrial stasis and poorly adherent mural thrombi, are an additional complication of AF. Of course, the most devastating complication in this regard is the occurrence of an embolic stroke. Approximately 15% of all strokes in the United States can be attributed to AF.[21] The average rate of ischemic stroke in patients with AF who are not receiving antithrombotic therapy is approximately 5% per year.[21,22] Stroke can precede the onset of documented AF, probably as a result of undetected paroxysms prior to the onset of established AF. The risk of stroke significantly increases with age, with the annual attributable risk increasing from 1.5% in individuals 50 to 59 years of age to almost 24% in those 80 to 89 years of age.[21] Patients with concomitant AF and rheumatic heart disease are at particularly high risk for stroke, with their risk being increased 17-fold compared to patients in SR.[21] Other risk factors for stroke identified from recent trials are previous ischemic stroke, transient ischemic attack, or other systemic embolic event; age >75 years; moderate or severe LV systolic dysfunction and/or congestive HF; hypertension; and diabetes.[21] The risk of stroke in patients with only atrial flutter has been traditionally believed to be low, prompting some to recommend only aspirin for prevention of thromboembolism in this particular patient population. However, because patients with atrial flutter may also intermittently have episodes of AF, this patient population also may be at risk for a thromboembolic event. Although the role of antithrombotic therapy

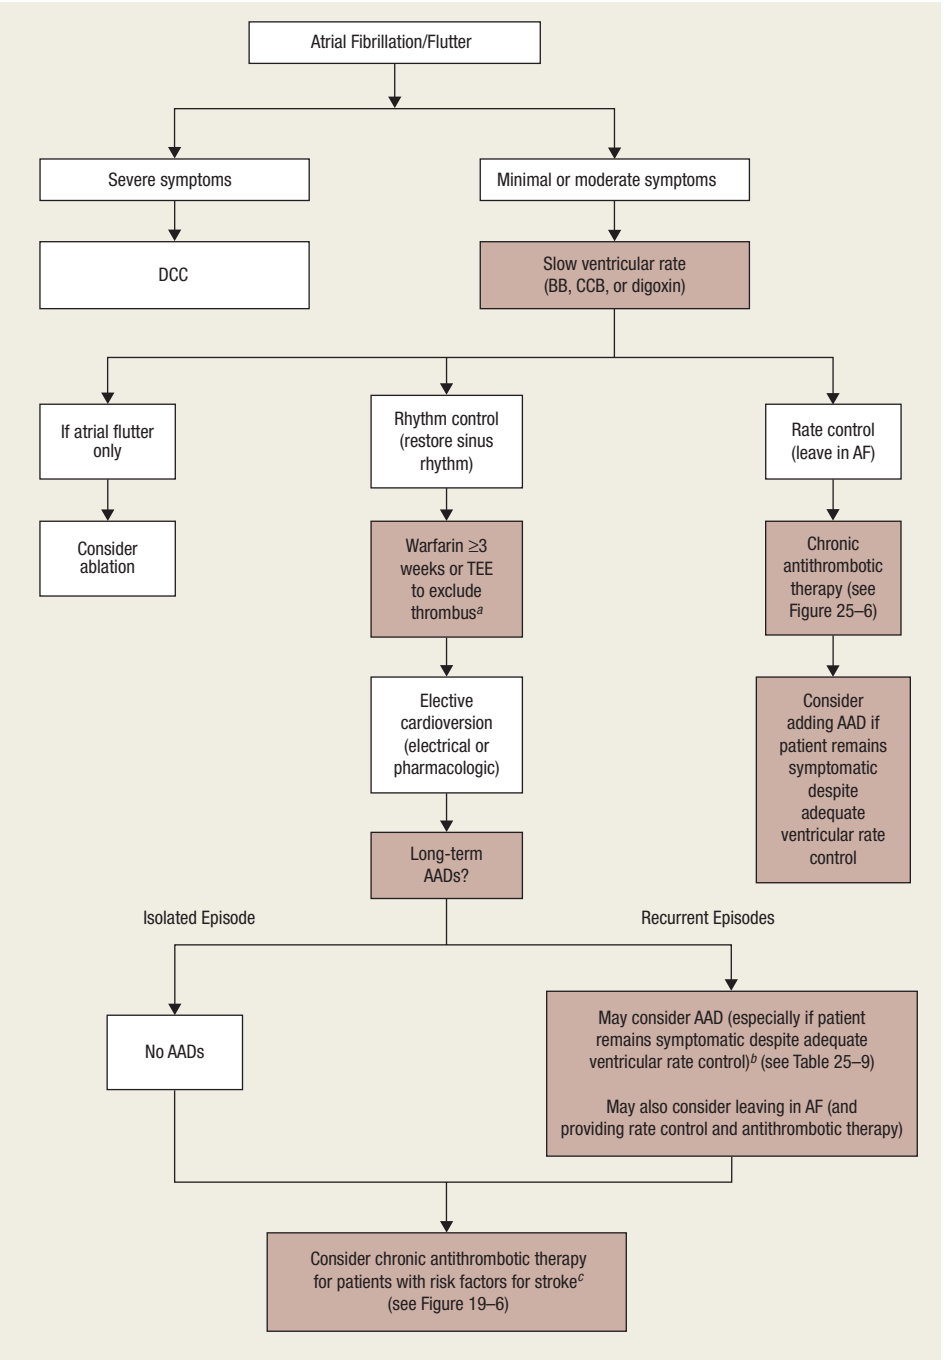

FIGURE 25-5. Algorithm for the treatment of AF and atrial flutter. [a]If AF <48 hours, anticoagulation prior to cardioversion is unnecessary; may consider TEE if patient has risk factors for stroke. [b]Ablation may be considered for patients who fail or do not tolerate ≥1 AAD. [c]Chronic antithrombotic therapy should be considered in all patients with AF and risk factors for stroke regardless of whether or not they remain in sinus rhythm. (AAD, antiarrhythmic drug; AF, atrial fibrillation; BB, β-blocker; CCB, calcium channel blocker [i.e., verapamil or diltiazem]; DCC, direct-current cardioversion; TEE, transesophageal echocardiogram)

in patients with atrial flutter has not been adequately studied in clinical trials, the most recent guidelines suggest that the same risk stratification scheme and antithrombotic recommendations used in patients with AF should also be applied to those with atrial flutter.[21]

Management

The traditional approach to the treatment of AF can be organized into several sequential goals. First, evaluate the need for acute treatment (usually administering drugs that slow ventricular rate). Next, contemplate methods to restore SR, taking into consideration the risks (e.g., thromboembolism). Lastly, consider ways to prevent the long-term complications of AF such as arrhythmia recurrence and thromboembolism. 4 One of the biggest controversies in the management of AF is whether restoring and maintaining SR is a desirable goal for all patients. A review of the management of AF and atrial flutter, including a discussion of this controversy, follows, organized according to the goals already outlined. Figure 25–5 shows an algorithm for the management of AF and atrial flutter. In addition, Table 25–8 summarizes the recommendations for pharmacologically controlling ventricular rate and restoring and maintaining SR from the most recent AF guidelines developed by the American College of Cardiology (ACC)/American Heart Association (AHA)/European Society of Cardiology (ESC).[17]

Acute Treatment First, consider the patient with new-onset, symptomatic AF or atrial flutter. Although uncommon, patients may present with signs and/or symptoms of hemodynamic instability (e.g., severe hypotension, angina, or pulmonary edema), which qualifies as a medical emergency. In these situations, DCC is indicated as first-line therapy in an attempt to immediately restore SR (without regard to the risk of thromboembolism). Atrial flutter often requires relatively low energy levels of countershock

TABLE 25-8 Evidence-Based Pharmacologic Treatment Recommendations for Controlling Ventricular Rate, Restoring Sinus Rhythm, and Maintaining Sinus Rhythm in Patients with Atrial Fibrillation

Treatment Recommendations	ACC/AHA/ESC Guideline Recommendation
Ventricular rate control (acute setting)	
In the absence of an accessory pathway, IV β-blockers or IV non-DHP CCBs are recommended for patients without hypotension or HF.	Class I
In the absence of an accessory pathway, IV digoxin or IV amiodarone is recommended for patients with HF.	Class I
IV amiodarone can be used to control the ventricular rate in patients who are refractory to or have contraindications to IV β-blockers, non-DHP CCBs, or digoxin.	Class IIa
IV procainamide or ibutilide is a reasonable alternative in patients with an accessory pathway when DCC is not necessary.	Class IIa
IV procainamide, ibutilide, or amiodarone may be considered for hemodynamically stable patients with an accessory pathway.	Class IIb
IV non-DHP CCBs are not recommended in patients with decompensated HF.	Class III
Ventricular rate control (chronic setting)	
Oral digoxin is effective for controlling the ventricular rate at rest in patients with HF or LV dysfunction, and in those who are sedentary.	Class I
Combination therapy with oral digoxin and either an oral β-blocker or non-DHP CCB is reasonable to control the ventricular rate both at rest and during exercise.	Class IIa
Oral amiodarone can be used when the ventricular rate cannot be adequately controlled at rest and during exercise with an oral β-blocker, non-DHP CCB, and/or digoxin.	Class IIb
Digoxin should not be used as the only agent for controlling the ventricular rate in patients with paroxysmal AF.	Class III
Restoration of sinus rhythm	
Flecainide, dofetilide, propafenone, or ibutilide is recommended for pharmacologic cardioversion of AF.	Class I
Amiodarone is a reasonable option for pharmacologic cardioversion of AF.	Class IIa
The "pill-in-the-pocket" approach (see text) can be used to terminate persistent AF on an outpatient basis once the treatment has been used safely in the hospital, in patients without sinus or AV node dysfunction, bundle-branch block, QT interval prolongation, Brugada syndrome, or SHD. (Note: AV node must be adequately blocked before initiating this therapy.)	Class IIa
Amiodarone can be used on an outpatient basis in patients with paroxysmal or persistent AF when rapid restoration of sinus rhythm is not necessary.	Class IIa
Quinidine or procainamide might be considered for pharmacologic cardioversion of AF, but their efficacy is not well established.	Class IIb
Digoxin and sotalol should not be used for pharmacologic cardioversion of AF (may be harmful).	Class III
Quinidine, procainamide, disopyramide, and dofetilide should not be initiated on an outpatient basis.	Class III
Maintenance of sinus rhythm	
Antiarrhythmic therapy can be useful for maintaining sinus rhythm and preventing tachycardia-induced cardiomyopathy.	Class IIa
Outpatient initiation of antiarrhythmic therapy is reasonable in patients without SHD.	Class IIa
Propafenone or flecainide may be initiated on an outpatient basis in patients with paroxysmal AF who have no SHD and are in sinus rhythm at the time therapy is initiated.	Class IIa
Sotalol may be initiated on an outpatient basis in patients without SHD, QT interval prolongation, electrolyte abnormalities, or other risk factors for proarrhythmia.	Class IIa
An antiarrhythmic drug should not be used when patients have risk factors for proarrhythmia with that particular agent.	Class III
Antiarrhythmic therapy is not recommended in patients with sinus or AV node dysfunction unless a pacemaker is present.	Class III

ACC, American College of Cardiology; AF, atrial fibrillation; AHA, American Heart Association; AV, atrioventricular; CCB, calcium channel blocker; DCC, direct-current cardioversion; DHP, dihydropyridine; ESC, European Society of Cardiology; HF, heart failure; IV, intravenous; LV, left ventricular; SHD, structural heart disease.

Adapted from Fuster et al.[17]

(i.e., 50 joules), whereas AF often requires higher energy levels (i.e., greater than 200 joules).

If patients are hemodynamically stable, there is no emergent need to restore SR. Instead, the focus should be directed toward controlling the patient's ventricular rate. Achieving adequate ventricular rate control should be a treatment goal for all patients with AF. To achieve this goal, drugs that slow conduction and increase refractoriness in the AV node (e.g., β-blockers, non-DHP CCBs, or digoxin) should be used as initial therapy. Although loading doses of digoxin have been historically recommended as first-line treatment to slow ventricular rate, use of this drug for this purpose, especially in patients with normal LV systolic function (LVEF >40%) has declined.[11] In this patient population, IV β-blockers (propranolol, metoprolol, esmolol), diltiazem, or verapamil are preferred. A few of the potential reasons for the declining use of digoxin in this patient population are its relatively slow onset and its inability to control the heart rate during exercise. Although an initial decrease in the ventricular rate can sometimes be observed within 1 hour of IV administration of digoxin, full control (heart rate <80 beats/min at rest and <100 beats/min during exercise) is usually not achieved for 24 to 48 hours. In addition, digoxin tends to be ineffective for controlling ventricular rate under conditions of increased sympathetic tone (i.e., surgery, thyrotoxicosis) because it slows AV nodal conduction primarily through vagotonic mechanisms. In contrast, IV β-blockers and non-DHP CCBs have a relatively quick onset and can effectively control the ventricular rate at rest and during exercise. β-blockers are also effective for controlling ventricular rate under conditions of increased sympathetic tone.

Based on the most recent guidelines for the treatment of AF, the selection of a drug to control ventricular rate in the acute setting should be primarily based on the patient's LV function.[17] In patients with normal LV function (LVEF >40%), IV β-blockers, diltiazem or verapamil is recommended as first-line therapy to control ventricular rate.[17] All of these drugs have proven efficacy in controlling the ventricular rate in patients with AF. Propranolol and metoprolol can be administered as intermittent IV boluses, whereas esmolol (because of its very short half-life of 5 to 10 minutes) must be administered as a series of loading doses followed by a continuous infusion. Likewise, because control of ventricular rate can be transient with a single bolus, verapamil or diltiazem can be given as an initial IV bolus followed by a continuous infusion.[23] These continuous infusions can be adjusted in monitored settings to the desired ventricular response (e.g., acutely <100 beats/min). In situations where AF or atrial flutter is precipitated by states of increased sympathetic tone, IV β-blockers can be highly effective and should be considered first.

In patients with LV dysfunction (LVEF ≤40%), both IV diltiazem and verapamil should be avoided because of their potent negative inotropic effects. IV β-blockers should be used with caution in this patient population and should be avoided if patients are in the midst of an episode of decompensated HF. In those patients who are having an exacerbation of HF symptoms, IV administration of either digoxin or amiodarone should be used as first-line therapy to achieve ventricular rate control.[17] IV amiodarone can also be used in patients who are refractory to or have contraindications to β-blockers, non-DHP CCBs, and digoxin.[17] However, clinicians should be aware that the use of amiodarone for controlling ventricular rate may also stimulate the conversion of AF to SR, and place the patient at risk for a thromboembolic event, especially if the AF has persisted at least 48 hours or is of unknown duration.

Patients may present with a slow ventricular response (in the absence of AV nodal-blocking drugs) and thus do not require therapy with β-blockers, non-DHP CCBs, or digoxin. This type of presentation should alert the clinician to the possibility of preexisting SA or AV nodal conduction disease such as sick sinus syndrome. In these patients, DCC should not be attempted without a temporary pacemaker in place.

Restoration of Sinus Rhythm? After treatment with AV nodal-blocking drugs and a subsequent decrease in the ventricular rate, the patient should be evaluated for the possibility of restoring SR if AF persists. Within the context of this evaluation, several factors should be considered. First, many patients spontaneously convert to SR without intervention, obviating the need for therapy to achieve this goal. For instance, AF occurs frequently as a complication of cardiac surgery and often spontaneously reverts to SR without therapy. Second, restoring SR is not a necessary or realistic goal in some patients. The results of six landmark clinical trials (Pharmacological Intervention in Atrial Fibrillation [PIAF], Rate Control versus Electrical Cardioversion for Persistent Atrial Fibrillation [RACE], Atrial Fibrillation Follow-up Investigation of Rhythm Management trial [AFFIRM], Strategies of Treatment of Atrial Fibrillation [STAF], How to Treat Chronic Atrial Fibrillation [HOT-CAFE], and Atrial Fibrillation and Congestive Heart Failure [AF-CHF]), have shed significant light on the comparative efficacy of rate-control (controlling ventricular rate; patient remains in AF) and rhythm-control (restoring and maintaining SR) treatment strategies in patients with AF.[24–29] The AFFIRM trial is the largest rate- versus rhythm-control study to be conducted to date in patients with AF.[26] In this trial, patients with AF and at least one risk factor for stroke were randomized to either a rate-control or rhythm-control group. Rate-control treatment involved AV nodal-blocking drugs (digoxin, β-blockers, and/or non-DHP CCBs) first, then nonpharmacologic treatment (AV nodal ablation with pacemaker implantation), if necessary. All patients in this group were anticoagulated with warfarin to achieve an international normalized ratio (INR) of 2.0 to 3.0. In the rhythm-control group, class I or III AADs were used to maintain SR. The choice of AAD therapy was left up to each patient's physician; however, by the end of the trial, more than 60% of patients had received at least one trial of amiodarone and approximately 40% of patients had received at least one trial of sotalol. In this group, anticoagulation was encouraged but could be discontinued if SR had been maintained for at least 4 weeks. After a mean follow-up period of 3.5 years, overall mortality was not statistically different between the two strategies but tended ($P = 0.08$) to be higher in the rhythm-control group. The results of the PIAF, RACE, STAF, and HOT-CAFE trials were consistent with those of the AFFIRM trial.[24,25,27,28] In addition, meta-analysis of the data from all of these trials demonstrated no significant difference in overall mortality between rate-control and rhythm-control strategies, which persisted even when the results from the AFFIRM trial were excluded from this analysis.[30]

Even though the results of the PIAF, RACE, STAF, HOT-CAFE, and AFFIRM trials collectively demonstrate that a rate-control strategy is a viable alternative to a rhythm-control strategy in patients with persistent AF, a significant limitation of these results is that they cannot be applied to patients with HF because only a small proportion of patients enrolled in these trials had LV systolic dysfunction. The AF-CHF trial was conducted to specifically evaluate the safety and efficacy of rate-control and rhythm-control strategies in patients with systolic HF.[29] In this trial, patients with an LVEF ≤35%, a history of congestive HF (defined as NYHA class II–IV HF within the past 6 months, NYHA class I HF with a hospitalization for HF during the previous 6 months, or an LVEF ≤25%), and a history of AF were randomized to either a rate-control or rhythm-control group. Rate-control treatment involved concomitant therapy with a β-blocker and digoxin first, then nonpharmacologic treatment (AV nodal ablation with pacemaker implantation), if necessary. In the rhythm-control group, amiodarone was the preferred AAD, whereas sotalol and dofetilide were considered alternatives (most of the patients ultimately received amiodarone). If patients in this group did not convert to SR within 6 weeks, electrical cardioversion was performed. Anticoagulation was recommended for all patients in both treatment groups. After a mean follow-up period of 37 months, no significant difference was observed between the treatment groups with regard to the primary end point of death from cardiovascular causes. Patients in the rhythm-control group tended to have more hospitalizations, primarily due to repeated cardioversions and adjustment of AAD therapy, compared with patients in the rate-control group, although this difference was not statistically significant ($P = 0.06$). It is important to note that the results of this trial should not be applied to patients with HF and preserved LV function (i.e., diastolic HF). Nevertheless, the results of this trial are generally consistent with those of the PIAF, RACE, AFFIRM, STAF, and HOT-CAFE trials and suggest that a rhythm-control strategy does not confer any advantage over a rate-control strategy in patients with AF and systolic HF.

Clearly, these important findings temper the old approach of aggressively attempting to maintain SR. Because a rhythm-control strategy does not offer any significant advantage over a rate-control strategy in the management of patients with persistent or recurrent AF (including those with concomitant HF), it is acceptable to allow patients to remain in AF, while being chronically treated not only with AV nodal-blocking drugs to achieve adequate ventricular rate control (e.g., heart rate <80 beats/min at rest and <100 beats/min during exercise) but also with appropriate antithrombotic therapy to prevent thromboembolic complications. 4 As in the acute setting, the selection of an AV nodal-blocking drug to control ventricular rate in the chronic setting should be primarily based on the patient's LV function.[17] In patients with normal LV function (LVEF >40%), oral β-blockers, diltiazem, or verapamil is preferred over digoxin because of their relatively quick onset and maintained efficacy during exercise. When adequate ventricular rate control cannot be achieved with one of these drugs, the addition of digoxin may provide an additive lowering of the heart rate. Verapamil and diltiazem should not be used in patients with LV dysfunction (LVEF ≤40%). Instead, β-blockers (i.e., metoprolol succinate, carvedilol, or bisoprolol) and digoxin are preferred in these patients, as these drugs are also concomitantly used to treat chronic HF. Specifically, in patients with NYHA class II or III HF, β-blockers should be considered over digoxin because of their survival benefits in patients with LV systolic dysfunction. If patients are having an episode of decompensated HF (NYHA class IV), digoxin is preferred as first-line therapy to achieve ventricular rate control

because of the potential for worsening HF symptoms with the initiation and subsequent titration of β-blocker therapy. If adequate ventricular rate control during rest and exercise cannot be achieved with β-blockers, non-DHP CCBs, and/or digoxin in patients with normal or depressed LV function, oral amiodarone can be used as alternative therapy to control the heart rate.[17]

Because a rate-control strategy is now considered a reasonable initial approach for the chronic management of AF, the question that remains to be answered is, "In which patients should restoration of SR be considered?" Electrical or pharmacologic cardioversion should be considered for those patients with AF who remain symptomatic despite having adequate ventricular rate control or for those patients in whom adequate ventricular rate control cannot be achieved. In addition, a rhythm-control strategy may be considered in patients who are experiencing their first episode of AF if they are likely to convert to and remain in SR. Chronic AAD therapy is usually not needed in this latter population since the AF is often self-limiting.

In those patients in whom it is decided to restore SR, one must consider that this very act (regardless of whether an electrical or pharmacologic method is chosen) places the patient at risk for a thromboembolic event. The reason for this is that the return of SR restores effective contraction in the atria, which may dislodge poorly adherent thrombi. Administering antithrombotic therapy prior to cardioversion not only prevents clot growth and the formation of new thrombi but also allows existing thrombi to become organized and well-adherent to the atrial wall. It is a generally accepted principle that patients become at increased risk of thrombus formation and a subsequent embolic event if the duration of the AF exceeds 48 hours. Therefore, it is vital for clinicians to estimate the duration of the patient's AF, so that appropriate antithrombotic therapy can be administered prior to cardioversion if needed.

According to the most recent guidelines on antithrombotic and thrombolytic therapy developed by the American College of Chest Physicians (ACCP), patients with AF lasting at least 48 hours or an unknown duration should receive warfarin treatment (target INR 2.5; range: 2.0 to 3.0) for at least 3 weeks prior to elective cardioversion.[21] After restoration of SR, full atrial contraction does not occur immediately. Rather, it returns gradually to a maximum contractile force over a 3- to 4-week period. Consequently, warfarin should be continued for at least 4 weeks after successful cardioversion and return of SR.[21] Patients with risk factors for thromboembolism should be continued on warfarin therapy for longer than 4 weeks unless it is definitively known that they are remaining in SR. If the 3 weeks of therapeutic warfarin therapy prior to cardioversion is not feasible, patients may alternatively undergo transesophageal echocardiography (TEE) to provide guidance regarding the need for antithrombotic therapy prior to cardioversion. If no thrombus is noted on TEE, then these patients can be cardioverted without the mandatory 3 weeks of warfarin pretreatment. However, IV unfractionated heparin should still be administered during the TEE and cardioversion procedure to prevent the formation of thrombi during the peri- and postcardioversion periods. After successful cardioversion and return of SR, these patients should receive 4 weeks of warfarin therapy, as their atria may still be mechanically stunned during this period. Patients with risk factors for thromboembolism should be continued on warfarin for longer than 4 weeks unless it is definitively known that they are remaining in SR. If the TEE performed prior to cardioversion reveals a thrombus, patients should then be anticoagulated indefinitely, and cardioversion should not be attempted until there is absence of thrombus on repeat TEE. Overall, the use of TEE in this manner has been compared to the conventional 3 weeks of anticoagulation before cardioversion in patients with AF.[31] In this large, multicenter, randomized trial, the incidence of thromboembolic events was not different between the two strategies, but bleeding episodes were higher in the group that received 3 weeks of warfarin therapy before cardioversion. Patients in the TEE strategy group had a higher success rate of achieving SR, probably because it is more difficult to terminate AF the longer a patient remains in this arrhythmia.

In patients with AF that is less than 48 hours in duration, anticoagulation prior to cardioversion is unnecessary because there has not been sufficient time to form atrial thrombi.[21] However, it is recommended that these patients should receive either IV unfractionated heparin or a low-molecular-weight heparin (subcutaneously at treatment doses) at presentation prior to cardioversion. If these patients have risk factors for stroke, a TEE could alternatively be performed prior to cardioversion to exclude the presence of thrombus. Patients with AF less than 48 hours in duration do not require the 4 weeks of postcardioversion anticoagulation therapy unless they have risk factors for stroke or the AF recurs.

After prior anticoagulation or TEE, the process of restoring SR can be considered. There are two methods of restoring SR in patients with AF or atrial flutter: pharmacologic cardioversion and DCC. The decision to use either of these methods is generally a matter of clinical preference. The disadvantages of pharmacologic cardioversion are the risk of significant side effects (e.g., drug-induced TdP),[32] the potential for drug–drug interactions (e.g., digoxin–amiodarone), and the lower efficacy of AADs when compared with DCC. The advantages of DCC are that it is quick and more often successful (80% to 90% success rate). The disadvantages of DCC are the need for prior sedation/anesthesia and a risk (albeit small) of serious complications such as sinus arrest or ventricular arrhythmias. Contrary to past beliefs, DCC carries very little risk in patients who are receiving digoxin and have no evidence of digoxin toxicity.

Nonetheless, despite the relatively high success rate associated with DCC, clinicians often elect to use AADs first, then resort to DCC in the event that these drugs fail. Pharmacologic cardioversion appears to be most effective when initiated within 7 days after the onset of AF.[17] According to the most recent treatment guidelines for AF, there is relatively strong evidence for efficacy of the class III pure I_K blockers (ibutilide and dofetilide), the class Ic AADs (e.g., flecainide and propafenone), and amiodarone (oral or IV) within this time frame.[17] Class Ia AADs have limited efficacy or have not been adequately studied in this setting. Sotalol is not effective for cardioversion of paroxysmal or persistent AF. Single, oral loading doses of propafenone (600 mg) and flecainide (300 mg) are effective compared with placebo for conversion of recent-onset AF and have been incorporated into the "pill-in-the-pocket" approach endorsed by the treatment guidelines.[17,33] With this method, outpatient, patient-controlled self-administration of a single, oral loading dose of either flecainide or propafenone can be a relatively safe and effective approach for the termination of recent-onset AF in a selected patient population that does not have sinus or AV node dysfunction, bundle-branch block, QT interval prolongation, Brugada syndrome, or SHD.[34] In addition, this treatment regimen should only be considered in patients who have previously been successfully cardioverted with these drugs on an inpatient basis. In patients with AF that is longer than 7 days in duration, only dofetilide, amiodarone, and ibutilide have proven efficacy for cardioversion.[17] The class Ia and Ic AADs have limited efficacy or have been inadequately studied in this setting.

Overall, when considering pharmacologic cardioversion, the selection of an AAD should be based on whether the patient has SHD (e.g., LV dysfunction, CAD, valvular heart disease, LV hypertrophy).[17] In the absence of any type of SHD, the use of a single, oral loading dose of flecainide or propafenone is a reasonable approach for cardioversion. Ibutilide can also be used as an alternative in this patient population; however, use of this agent is restricted to a

monitored setting in the hospital because it requires QT interval monitoring. In patients with underlying SHD, flecainide, propafenone, and ibutilide should be avoided because of the increased risk of proarrhythmia; amiodarone or dofetilide should be used instead. Although amiodarone can be administered safely on an outpatient basis because of its low proarrhythmic potential, dofetilide therapy can only be initiated in the hospital (for QT interval monitoring). Additionally, it should be remembered that a patient's ventricular rate should be adequately controlled with AV nodal-blocking drugs prior to administering a class Ic (or Ia) AAD for cardioversion. The class Ia and Ic AADs may paradoxically increase ventricular response. Traditionally, this observation has been attributed to the vagolytic action of these drugs despite the fact that only disopyramide displays significant anticholinergic side effects. Therefore, a more likely alternative explanation exists: all of these drugs slow atrial conduction, decreasing the number of impulses reaching the AV node; as a result, the AV node paradoxically allows more impulses to gain entrance to the ventricular conduction system, thereby increasing ventricular rate.

Long-Term Complications There are two forms of therapy that the clinician must consider in each patient with AF: long-term antithrombotic therapy to prevent stroke, and long-term AADs to prevent recurrences of AF. Consider the issue of antithrombotic therapy first. In the past, patients with AF were not routinely anticoagulated (unless there was a history of stroke or concurrent mitral valve disease) because it was believed that the risk of warfarin exceeded its potential (though unknown) benefit. In the past several years, numerous randomized, placebo-controlled trials have demonstrated that warfarin is the most effective agent for preventing stroke in patients with AF. The results of these studies have been incorporated into the most recent ACCP guidelines for antithrombotic therapy in patients with AF.[21] When initiating chronic antithrombotic therapy in patients with AF, assessing the patient's risk for stroke becomes important for selecting the most appropriate regimen. Based on the most recent ACCP guidelines, the CHADS2 index is now recommended for stroke risk stratification in patients with AF.[21] With this risk index, patients with AF are given two points if they have a history of a previous stroke or transient ischemic attack, and one point each for being ≥75 years old, having hypertension, having diabetes, or having congestive HF (CHADS2 is an acronym for each of these risk factors). The points are added up and the total score is then used to determine the most appropriate antithrombotic therapy for the patient (Fig. 25–6). Patients with a CHADS2 score of ≥2 are considered to be at high risk for stroke and should receive warfarin (target INR: 2.5; range: 2.0 to 3.0). Patients with a CHADS2 score of 1 are considered to be at intermediate risk for stroke and should receive either warfarin (target INR: 2.5; range: 2.0 to 3.0) or aspirin (75 to 325 mg/day). However, because of its superior efficacy in preventing stroke, the use of warfarin is suggested over that of aspirin in this particular group of patients. Patients with a CHADS2 score of 0 are considered to be at low risk for stroke and should receive aspirin (75 to 325 mg/day).

The safety and efficacy of combination antithrombotic therapy with aspirin and clopidogrel in patients with AF has been recently investigated in the Atrial Fibrillation Clopidogrel Trial with

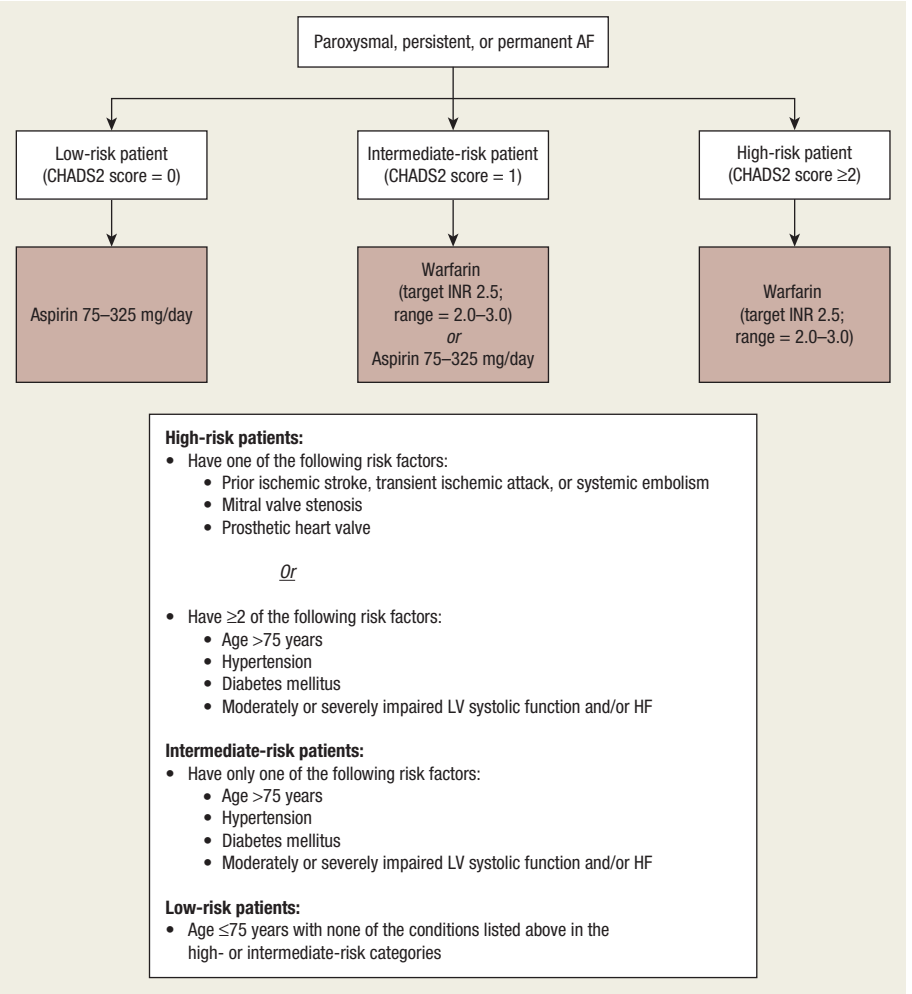

FIGURE 25-6. Algorithm for the prevention of thromboembolism in paroxysmal, persistent, or permanent AF.[a] The target INR for patients with prosthetic heart valves should be based upon the type of valve that is present. (AF, atrial fibrillation; INR, international normalized ratio; HF, heart failure; LV, left ventricular)

Irbesartan for Prevention of Vascular Events (ACTIVE) research program. Both the ACTIVE W and ACTIVE A evaluated the efficacy and safety of this combination therapy in patients with AF and at least one risk factor for stroke.[35,36] In the ACTIVE W, patients were randomized to receive oral anticoagulation therapy (with the vitamin K antagonist used in the investigator's country) titrated to achieve a target INR of 2.0 to 3.0 or clopidogrel 75 mg/day plus aspirin 75 to 100 mg/day.[35] After a median follow-up of 1.3 years, this trial was prematurely discontinued when the oral anticoagulation therapy was found to be superior to the combination antiplatelet regimen in reducing the occurrence of stroke, non–central nervous system systemic embolism, MI, or vascular death. While major bleeding events were similar between the two groups, significantly more minor bleeding episodes occurred in the clopidogrel plus aspirin group than in the oral anticoagulation group.

Patients who had a contraindication to or were unwilling to take oral anticoagulant therapy were enrolled in the ACTIVE A.[36] In this trial, patients were randomly assigned to receive clopidogrel 75 mg/day plus aspirin 75 to 100 mg/day or aspirin monotherapy (75 to 100 mg/day). After a median follow-up of 3.6 years, the incidence of stroke, non–central nervous system systemic embolism, MI, or vascular death was significantly reduced in the clopidogrel plus aspirin group when compared with the aspirin group. However, significantly more patients in the clopidogrel plus aspirin group experienced major bleeding than in the aspirin group. While the results of ACTIVE W were evaluated when the most recent ACCP guidelines were developed, the ACTIVE A was published after this time period. Although no official recommendations regarding the use of clopidogrel and aspirin therapy in patients with AF have been published, based on the results of ACTIVE A, this combination regimen may be considered in patients who are deemed to be unsuitable candidates for warfarin therapy (e.g., unable to comply with monitoring or dosing regimen requirements). If these patients are considered to be at high risk for bleeding, aspirin monotherapy can then be used.

Although it was previously an acceptable practice to continue antithrombotic therapy for only 4 weeks after successful cardioversion (with the belief that a patient's risk for thromboembolism had abated since they were in SR), data from the RACE and AFFIRM trials, in particular, strongly suggest that patients with AF and other risk factors for stroke continue to be at risk for stroke even when maintained in SR.[25,26] It is possible that these patients may be having undetected episodes of paroxysmal AF, placing them at risk for stroke. Consequently, the most recent ACCP guidelines recommend that chronic antithrombotic therapy be considered for all patients with AF and risk factors for stroke regardless of whether or not they remain in SR.[21]

The second form of chronic therapy to be considered is AADs to prevent recurrences of AF. Historically, many clinicians have aggressively attempted to maintain SR by prescribing oral AADs (usually quinidine) to prevent AF recurrences despite the fact that only small studies with conflicting results existed evaluating this approach. To evaluate the efficacy of quinidine in preventing AF, a well-known meta-analysis of the existing literature was completed.[37] This meta-analysis demonstrated that indeed more patients remain in SR with quinidine therapy (compared to placebo); however, approximately 50% have recurrences of AF within a year despite quinidine. This reported effectiveness was at the cost of an associated increase in mortality (presumably due, in part, to proarrhythmia) in the quinidine-treated patients. These disturbing results (published soon after the CAST[38]) became widely quoted and highly visible, making clinicians question the wisdom of long-term prevention of recurrences of AF with AADs. These results coupled with the more recent findings of the PIAF, RACE, AFFIRM, STAF, HOT-CAFE, and AF-CHF trials question the need to use AADs to prevent AF recurrences.[20–24] In fact, based on the results of these landmark trials, the use of AADs to maintain SR may be more reasonable to consider in patients who remain symptomatic despite having adequate ventricular rate control or for those patients in whom adequate ventricular rate control cannot be achieved.

TABLE 25-9 Guidelines for Selecting Antiarrhythmic Drug Therapy for Maintenance of Sinus Rhythm in Patients with Recurrent Paroxysmal or Recurrent Persistent Atrial Fibrillation

No structural heart disease[a]
First line: flecainide, propafenone, or sotalol
Second line: amiodarone, dofetilide, or dronedarone (catheter ablation could also be considered as an alternative to antiarrhythmic therapy)
Heart failure[a]
First line: amiodarone or dofetilide
Second line: catheter ablation
Coronary artery disease[a]
First line: sotalol (to be used only if patients have normal LV systolic function)
Second line: amiodarone, dofetilide, or dronedarone[b] (catheter ablation could also be considered as an alternative to antiarrhythmic therapy)
Hypertension[a]
Presence of significant LVH
First line: amiodarone
Second line: catheter ablation
Absence of significant LVH:
First line: flecainide, propafenone, or sotalol
Second line: amiodarone, dofetilide, or dronedarone (catheter ablation could also be considered as an alternative to antiarrhythmic therapy)

LV, left ventricular; LVH, left ventricular hypertrophy.
[a]Drugs are listed alphabetically and not in order of suggested use.
[b]Dronedarone should only be used in this situation if the patient has normal LV systolic function.

According to the most recent treatment guidelines for AF, the class Ic or III AADs are reasonable to consider to maintain patients in SR (Table 25–9).[17] The role of the class Ia AADs for maintenance of SR has been deemphasized throughout these guidelines as they are considered less effective or incompletely studied compared to the class Ic and III AADs. Realistically, however, these drugs can still be considered as last-line therapy in select patients. Interestingly, a recent systematic review of AADs for the maintenance of SR after cardioversion in patients with AF demonstrated that AF recurrences were significantly reduced with the use of class Ia, Ic, and III AADs; however, mortality was significantly increased with the class Ia drugs, in particular.[39]

The class Ic AADs, flecainide and propafenone, are effective for maintaining SR. However, because of the increased risk for proarrhythmia, these drugs should be avoided in patients with SHD.

Although all of the oral class III AADs have demonstrated efficacy in preventing AF recurrences, amiodarone is clearly the most effective agent and is now the most frequently used AAD despite its potential for causing significant organ toxicity.[11] The superiority of amiodarone over other AADs for maintaining patients in SR has been demonstrated in a number of clinical trials. In the Canadian Trial of Atrial Fibrillation, amiodarone was significantly more effective than sotalol or propafenone in maintaining SR in patients with persistent or paroxysmal AF.[40] Furthermore, in a substudy of the AFFIRM trial, amiodarone appeared to be the most effective AAD of those used in the study.[41] In the Sotalol Amiodarone Atrial Fibrillation Efficacy Trial, amiodarone and sotalol were equally effective at converting AF to SR.[42] However, amiodarone was significantly more effective than sotalol at maintaining SR in all patient subgroups, except for those with CAD where the efficacy of these two drugs was comparable.

Although sotalol is not effective for conversion of AF, it is an effective drug for maintaining SR. Sotalol has been shown to be

at least as effective as quinidine or propafenone in preventing recurrences of AF.[40,43] However, treatment with either quinidine or sotalol is associated with a similar incidence of TdP. Because this form of proarrhythmia primarily occurs with higher doses of sotalol (quinidine usually causes TdP at low or therapeutic concentrations), it may be more easily predicted and therefore avoided. Nonetheless, sotalol may increase mortality in patients with AF similar to quinidine; however, this requires further study.[44]

Dofetilide is effective in preventing recurrences of AF[45] but has not been directly compared with either amiodarone or sotalol. In a large, multicenter trial,[46] dofetilide (dose adjusted for renal function and QT interval) was more effective than placebo in maintaining SR (approximately 35% to 50% at 1 year). The efficacy of dofetilide for the maintenance of SR has also specifically been demonstrated in patients with LV dysfunction.[47] Like sotalol and quinidine, dofetilide also has significant potential to cause TdP (in a dose-related fashion).

The safety and efficacy of dronedarone for the treatment of AF and atrial flutter have been evaluated in several clinical trials. In the European Trial in Atrial Fibrillation or Flutter Patients Receiving Dronedarone for the Maintenance of Sinus Rhythm and the American-Australian-African Trial with Dronedarone in Atrial Fibrillation or Flutter Patients for the Maintenance of Sinus Rhythm, which were similar in design, dronedarone was more effective than placebo in maintaining SR in patients with paroxysmal or persistent AF or atrial flutter.[48] In another trial, the use of dronedarone in patients with persistent or paroxysmal AF or atrial flutter was associated with significantly fewer hospitalizations due to cardiovascular events or death when compared to placebo.[49] The safety and efficacy of dronedarone were also evaluated in a trial that included patients with NYHA class III or IV HF and an LVEF of 35% or less.[50] This trial was prematurely terminated because all-cause mortality (primarily due to worsening HF) was significantly higher in the dronedarone group when compared with the placebo group. Consequently, based on these findings, dronedarone is contraindicated in and has received a black-box warning for patients with advanced HF (NYHA class IV or NYHA class II or III with a recent hospitalization for decompensated HF).

Overall, the selection of an AAD to maintain SR should be primarily based on whether the patient has SHD.[17] However, other factors, including renal and hepatic function, concomitant disease states and drugs, and the AAD's side effect profile, also need to be considered. For those patients with no underlying SHD, flecainide, propafenone, or sotalol should be considered initially because these drugs have the most optimal long-term safety profile in this setting. However, amiodarone, dofetilide, or dronedarone could be used as alternative therapy if the patient fails or does not tolerate one of these initial AADs. In the presence of SHD, flecainide and propafenone should be avoided because of the risk of proarrhythmia. If LV dysfunction is present (LVEF ≤40%), amiodarone should be considered the AAD of choice. Dofetilide can be used as an alternative if patients develop intolerable side effects with amiodarone. At this time, only amiodarone and dofetilide have been shown to be mortality-neutral in patients with AF and HF. Both dronedarone and sotalol should be avoided in patients with LV dysfunction because of the risk for increased mortality (dronedarone) or worsening HF (sotalol). In patients with CAD, sotalol can be used initially, provided that the patient's LV function is normal. Amiodarone, dofetilide, or dronedarone could be used as an alternative therapy if the patient fails or does not tolerate sotalol. The presence of LV hypertrophy may predispose the myocardium to proarrhythmic events. Because of its low proarrhythmic potential, amiodarone should be considered first-line therapy in these patients.

Nonpharmacologic forms of therapy, designed to maintain SR are becoming increasingly popular treatment options for patients with AF or atrial flutter. For patients who have "pure" (i.e., not associated with concurrent AF) type I atrial flutter, ablation of the reentrant substrate with radiofrequency current is highly effective (~90%)[51] and can be considered first-line treatment of atrial flutter to prevent recurrences.[52] Catheter ablation for patients with AF is much more technically difficult for a variety of reasons, including the lack of a single, identifiable, and ablatable reentrant focus (as in atrial flutter). Nonetheless, progress has been made in this area. Patients with AF have been found to have arrhythmogenic foci that occur in atrial tissue near and within the pulmonary veins. During the ablation procedure, radiofrequency energy can be delivered to these areas in an attempt to abolish the foci. Historically, this procedure was often considered last-line therapy for patients who had failed all AADs, including amiodarone. However, in some of the recent trials, the use of catheter ablation in patients with AF has been associated with a significant reduction in recurrent episodes of AF and an improvement in quality of life when compared with AAD therapy.[53,54] There is even some evidence[55,56] to suggest that this procedure may be superior to AADs as first-line therapy of symptomatic AF; however, these results will have to be validated in larger trials. Based on these recent data, the guidelines now recommend that catheter ablation be considered as a reasonable treatment alternative for patients with symptomatic episodes of recurrent AF who fail or do not tolerate at least one class I or III AAD.[57] This procedure is not without its risks, as major complications, such as pulmonary vein stenosis, thromboembolic events, cardiac tamponade, and new atrial flutter, have been reported in up to 6% of patients.[58]

PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA CAUSED BY REENTRY

PSVT arising by reentrant mechanisms includes those arrhythmias caused by AV nodal reentry, AV reentry incorporating an anomalous AV pathway, SA nodal reentry, and intraatrial reentry. AV nodal reentry and AV reentry are by far the most common of these tachycardias. 5

Mechanisms

The underlying substrate of AV nodal reentry is the functional division of the AV node into two (or more) longitudinal conduction pathways or "dual" AV nodal pathways.[59] It is now clear that there are not two distinct anatomic pathways inside the AV node itself; rather, it is likely that a fanlike network of perinodal fibers inserts into the AV node and represents the second pathway. The pathways possess key differences in conduction characteristics: one is a fast-conducting pathway with a relatively long refractory period (fast pathway), and the other is a slower-conducting pathway with a shorter refractory period (slow pathway). The presence of dual pathways does not necessarily imply that the patient will have clinical PSVT. In fact, it is estimated that between 10% and 50% of patients have discernible dual pathways, but the incidence of PSVT is considerably lower.[59] Sustenance of the tachycardia depends on the critical electrophysiologic discrepancies and the ability of one pathway (usually the slow) to allow repetitive antegrade conduction, and the ability of the other pathway (usually the fast) to allow repetitive retrograde conduction. During SR, a patient with dual pathways conducts supraventricular impulses antegrade through both pathways. Electrical activity reaches the distal common pathway at the level of or above the His bundle and continues to depolarize the ventricles in an antegrade direction. Conduction proceeds via the two pathways but reaches the distal common pathway first through the fast AV nodal route (Fig. 25–7). For this reason, a short PR interval is sometimes observed during SR.

PSVT caused by AV nodal reentry may occur by the following sequence of events. The occurrence of an appropriately timed premature impulse penetrates the AV node but is blocked in the fast pathway that is still refractory from the previous beat. However,

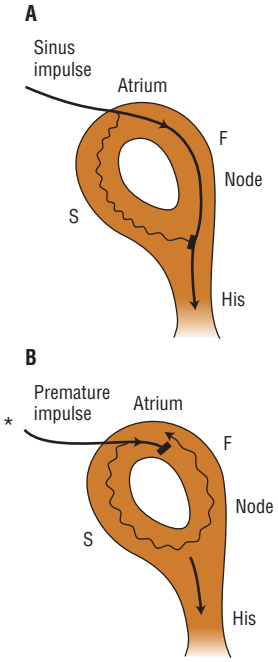

FIGURE 25-7. Reentry mechanism of dual AV nodal pathway PSVT. *A.* Sinus rhythm: The impulse travels from the atrium through the fast pathway *(F)* and then to the His-Purkinje system *(His)*. The impulse also travels through the slow pathway *(S)* but is stopped when refractory tissue is encountered. *B.* Dual AV nodal reentry: A critically timed premature impulse (*) is stopped in the fast pathway (because of prolonged refractoriness) but is able to travel antegrade down the slow pathway and retrograde through the fast pathway. (AV, atrioventricular; PSVT, paroxysmal supraventricular tachycardia)

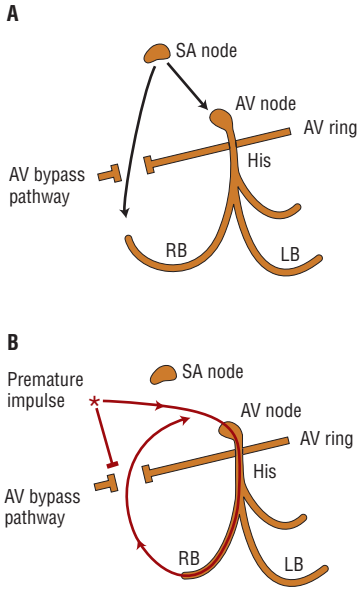

FIGURE 25-8. Reentry mechanism for AV accessory pathway PSVT in Wolff-Parkinson-White syndrome. *A.* Sinus rhythm: The impulse travels from the atrium to the ventricle by two pathways—the AV node and an accessory bypass pathway. *B.* AV reentry: A critically timed premature impulse (*) is stopped in the Kent bundle (because of prolonged refractoriness) but travels antegrade through the AV node and retrograde through the Kent bundle. (AV, atrioventricular; His, His-Purkinje system; LB, left bundle-branch; PSVT, paroxysmal supraventricular tachycardia; RB, right bundle-branch; SA, sinoatrial)

the slow pathway, which has a shorter refractory period, permits antegrade conduction of the premature impulse. By the time the impulse has reached the distal common pathway, the fast pathway has recovered its excitability and now will permit retrograde conduction. The impulse reaches the common proximal pathway, preceded by an excitable gap of tissue, and reenters the slow pathway. A reentrant circuit that does not require atrial or ventricular tissue is completed within the AV node, and a tachycardia is thereby initiated (see Fig. 25–7). The common form of this tachycardia uses the slow pathway for antegrade conduction and the fast pathway for retrograde conduction; an uncommon form exists in which the reentrant impulse travels in the opposite direction.

AV reentrant tachycardia depends upon the presence of an anomalous, or accessory, extranodal pathway that bypasses the normal AV conduction pathway. Several different types of accessory pathways have been described, depending on the specific anatomic areas they connect (e.g., AV bundles or nodoventricular tracts); some are also referred to as eponyms, such as the Kent bundle. A Kent bundle is an extranodal AV connection that is associated with WPW syndrome. During SR (Fig. 25–8), patients with WPW syndrome depolarize the ventricles simultaneously through both AV pathways (AV nodal pathway and the Kent bundle), creating a fusion pattern on the early portion of the QRS complex (delta wave). The degree of ventricular "preexcitation" depends on the contribution of antegrade ventricular activation through the accessory pathway. Patients may have an accessory pathway that is not evident on ECG, which is referred to as a "concealed" Kent bundle. These concealed accessory pathways are often incapable of antegrade conduction and can only accept electrical stimulation in a retrograde fashion. The electrocardiographic expression of preexcitation (delta wave) depends on the location of the accessory pathway, the distance from the wavefront of sinus activation, and the conduction characteristics of the various structures involved. It should be noted that (similar to patients with dual AV nodal pathways) not all patients with preexcitation with an accessory AV pathway are capable of having clinical PSVT.

Patients with an accessory AV pathway may have three forms of supraventricular tachycardia: orthodromic reentry, antidromic reentry, and/or AF or atrial flutter. AV reentrant PSVT usually occurs by the following sequence of events. Analogous to AV nodal reentry, two pathways (the normal AV nodal pathway and the accessory AV pathway) exist that have different electrophysiologic characteristics. The AV nodal pathway usually has a relatively slower conduction velocity and shorter refractory period, and the accessory pathway has a faster conduction velocity and a longer refractory period. A critically timed premature impulse may be blocked in the accessory pathway because this area is still refractory from the previous sinus beat. However, the AV nodal pathway, with a relatively shorter refractory period, may accept antegrade conduction of the premature impulse. Meanwhile, the accessory pathway may recover its excitability and now allow retrograde conduction. A macroreentrant tachycardia is thereby initiated in which the antegrade pathway is the AV nodal pathway; the distal common pathway is the ventricle; the retrograde pathway is the accessory pathway; and the proximal common pathway is the atrium (see Fig. 25–8). This sequence of events (down the AV node, up the Kent bundle), termed *orthodromic PSVT*, is the common variety of reentry in patients with an accessory AV pathway, resulting in a narrow QRS tachycardia. In the uncommon variety, conduction proceeds in the opposite direction (down the Kent bundle, up the AV node), resulting in a wide QRS tachycardia, which is termed *antidromic PSVT*. Patients with WPW syndrome can have a third type of tachycardia, namely AF. The occurrence of AF in the setting of an accessory AV pathway (i.e., WPW syndrome) can be extremely serious. As AF is an extremely rapid atrial tachycardia, conduction can proceed down the accessory AV pathway, resulting in a very fast ventricular response or even VF. Unlike the AV nodal

pathway, the refractory period of the accessory bundle shortens in response to rapid stimulation rates.

Sinus node reentry and intraatrial reentry occur less commonly and are not as well described as AV nodal reentry and AV reentry. Aside from a characteristic abrupt onset and termination, coupled with subtle changes in P-wave morphology, these tachycardias can be difficult to diagnose. Electrophysiologic studies may be necessary to determine the ultimate mechanism of the PSVT.

Management

Both pharmacologic and nonpharmacologic methods have been used to treat patients with PSVT. Drugs used in the treatment of PSVT can be divided into three broad categories: (a) those that directly or indirectly increase vagal tone to the AV node (e.g., digoxin); (b) those that depress conduction through slow, calcium-dependent tissue (e.g., adenosine, β-blockers, and non-DHP CCBs); and (c) those that depress conduction through fast, sodium-dependent tissue (e.g., quinidine, procainamide, disopyramide, and flecainide). Drugs within these categories alter the electrophysiologic characteristics of the reentrant substrate so that PSVT cannot be sustained. In PSVT caused by AV nodal reentry, class I AADs, such as flecainide, act primarily on the retrograde fast pathway. Digoxin and β-blockers may work on either the retrograde fast or the antegrade slow pathway. Verapamil, diltiazem, and adenosine prolong conduction time and increase refractoriness, primarily in the slow antegrade pathway of the reentrant loop. In PSVT caused by AV reentry incorporating an extranodal pathway, class I AADs increase refractoriness in the fast accessory pathway or within the His-Purkinje system. β-blockers, digoxin, adenosine, and verapamil all act by their effects on the AV nodal (antegrade, slow) portion of the reentrant circuit. Regardless of the mechanism, treatment measures are directed first at terminating an acute episode of PSVT and then at preventing symptomatic recurrences of the arrhythmia.

For those patients with PSVT who present with severe symptoms (i.e., syncope, near syncope, angina, or severe HF), synchronized DCC is the treatment of choice. Even at low energy levels (such as 25 joules), DCC is almost always effective in quickly restoring SR and correcting symptomatic hypotension. Patients with only mild to moderate symptoms usually do not require DCC, and nonpharmacologic measures that increase vagal tone to the AV node can be used initially. Vagal techniques, such as unilateral carotid sinus massage, Valsalva maneuver, ice water facial immersion, or induced retching, are often successful in terminating PSVT, although carotid massage and Valsalva maneuver are the simplest, least obtrusive, and most frequently used of these techniques.

In the event that vagal maneuvers fail (approximately 80% of acute episodes) in those patients with tolerable symptoms, drug therapy is the next option. Figure 25–9 shows a therapeutic approach to the acute treatment of the different forms of reentrant PSVT. 6 This approach is based on analysis of the electrocardiographic characteristics of the rhythm because PSVT is not always discernible from other arrhythmias, and some forms of PSVT require different treatment. In patients with a narrow QRS, regular arrhythmia (AV nodal reentry

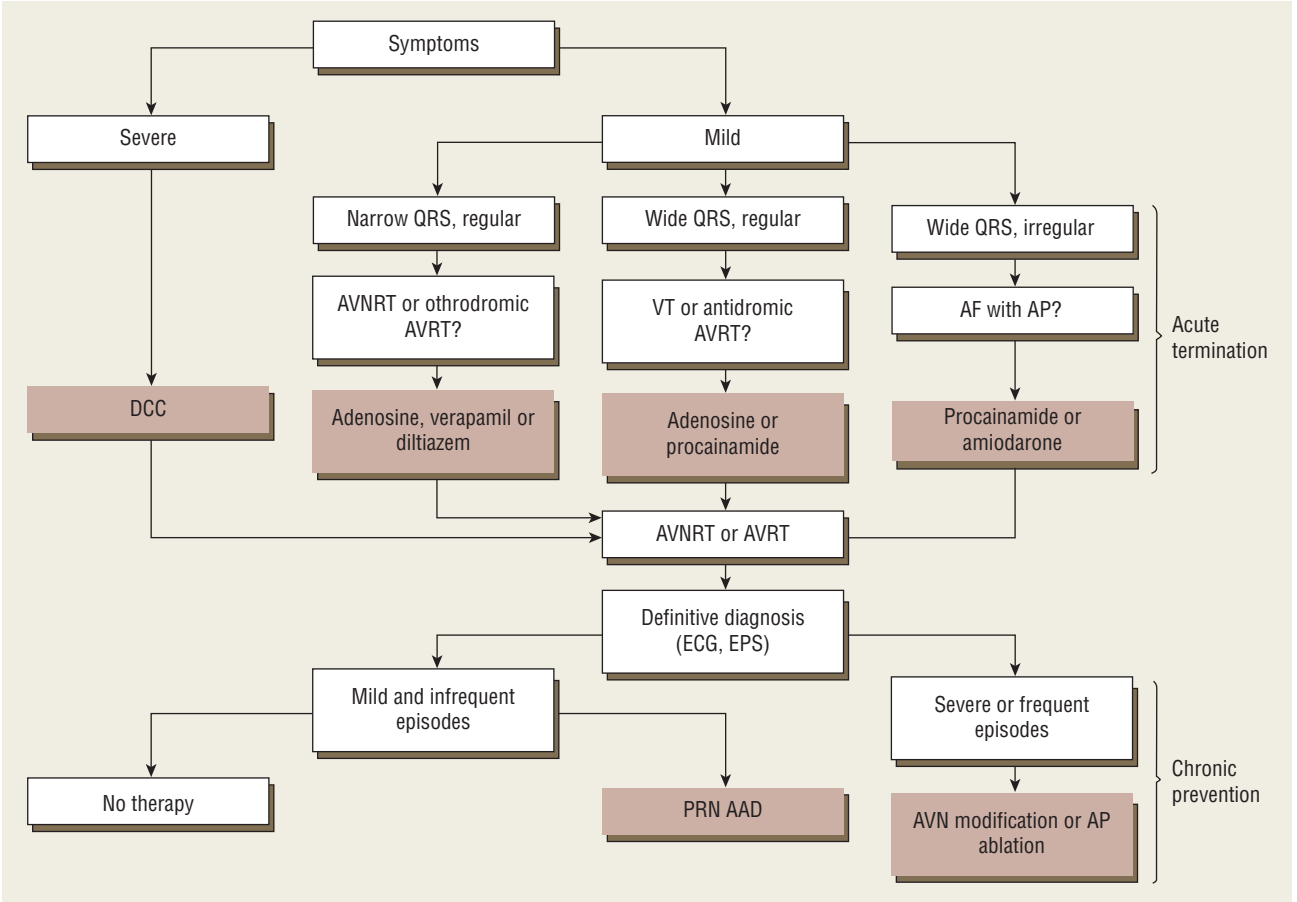

FIGURE 25-9. Algorithm for the treatment of acute *(top portion)* PSVT and chronic prevention of recurrences *(bottom portion)*. *Note:* For empiric bridge therapy prior to radiofrequency ablation procedures, CCBs (or other AV nodal blockers) should not be used if the patient has AV reentry with an accessory pathway. (AAD, antiarrhythmic drugs; AF, atrial fibrillation; AP, accessory pathway; AV, atrioventricular; AVN, atrioventricular nodal; AVNRT, atrioventricular nodal reentrant tachycardia; AVRT, atrioventricular reentrant tachycardia; CCBs, calcium channel blockers; DCC, direct-current cardioversion; ECG, electrocardiogram; EPS, electrophysiologic studies; PRN, as needed; PSVT, paroxysmal supraventricular tachycardia; VT, ventricular tachycardia.)

or orthodromic AV reentry), IV verapamil (5 to 10 mg), IV diltiazem (15 to 25 mg), and adenosine (6 to 12 mg) are all equally efficacious. Approximately 80% to 90% of PSVT episodes will revert to SR within 5 minutes of these drug therapies.[60] The most recent guidelines for cardiopulmonary resuscitation (CPR) and emergency cardiovascular care (ECC) from the AHA,[61] and practice guidelines from the ACC/AHA/ESC,[52] promote adenosine as the drug of first choice in patients with PSVT. 5 These recommendations are particularly important when treating a patient who presents with a wide QRS, regular tachycardia that may be VT or PSVT (antidromic AV reentry or as a result of aberrancy). Because of its ultrashort duration of action (seconds), adenosine will not cause the severe and prolonged hemodynamic compromise seen in patients with VT who were mistakenly treated with verapamil and suffered from its negative inotropic effects and vasodilator properties.[62] If, in fact, the arrhythmia is PSVT, adenosine will likely terminate it. An alternative treatment for this type of patient is IV procainamide, which works on the fast, sodium-dependent extranodal pathway and is also effective for VT. Likewise, IV procainamide, or perhaps IV amiodarone (particularly in patients with LV dysfunction), or IV sotalol should be used for the patient who presents with a wide QRS, irregular arrhythmia that is hemodynamically stable.[61] This rhythm could represent AF with rapid ventricular activation occurring primarily through an extranodal pathway. Administration of IV verapamil, diltiazem, digoxin, or adenosine to these patients may result in a paradoxical increase in ventricular response, causing severe symptoms requiring cardioversion. Consequently, these drugs are considered contraindicated in this specific setting.

Once the acute episode of PSVT is terminated, a decision on long-term preventive therapy must follow. Most patients require long-term therapy; preventive treatment is indicated if (a) frequent episodes occur that necessitate therapeutic intervention (i.e., emergency department visits or interference with the patient's lifestyle), or (b) infrequent but severely symptomatic symptoms occur. For those patients in whom a preventive treatment is deemed necessary, two methods of management have been used: preventive drug therapy and ablation.

AADs are no longer the treatment of choice to prevent recurrences of reentrant PSVT for the following reasons: (a) lifelong treatment is necessary in these generally young, but otherwise healthy, individuals; (b) there are few, if any, large controlled or comparative trials to assist the clinician in rationally choosing effective agents; and (c) most importantly, other nonpharmacologic treatments are clearly more effective. Nevertheless, drug therapy may occasionally be necessary in some patients, particularly those with mild symptoms and infrequent recurrences. A trial-and-error approach may be used, complemented by the use of ambulatory electrocardiographic recordings (Holter) or telephonic transmissions of cardiac rhythm (event monitors) to objectively document the efficacy or failure of the chosen drug regimen. Drugs known to be effective in preventing recurrences of PSVT are the AV nodal-blocking drugs (digoxin, β-blockers, non-DHP CCBs, and combinations of these agents) and the class Ic AADs (flecainide, propafenone). Drugs such as quinidine, disopyramide, amiodarone, and dofetilide, although effective in some patients, should be discouraged because of the risk of toxicity with long-term treatment.

One concept that can serve as an aid to arriving at an effective regimen is that there are patterns of drug response in patients with PSVT; in other words, the tachycardia behaves as if it has a "weak link." Patients who respond to agents that act on one limb of the reentrant loop are less likely to respond to drugs that block conduction in the other limb. For instance, in a patient with AV nodal reentry, one may first choose a non-DHP CCB or β-blocker (to affect the antegrade, slow pathway). If symptomatic recurrences are subsequently documented, it may be prudent to switch to a class Ic AAD (to affect the retrograde, fast pathway) in an attempt to find the weak link or susceptible pathway. Patients with evidence of preexcitation (delta waves during SR) should not be treated with only AV nodal-blocking drugs. If AF were to occur, these drugs would facilitate rapid conduction over the accessory pathway. The trial-and-error method for determining drug effectiveness in this setting has inherent shortcomings. If the PSVT episodes are infrequent, a considerable time period may be consumed before an effective regimen is realized, or in the case of moderate to severe symptoms associated with PSVT, the patient may experience several troublesome episodes before the correct drug is identified. Alternatively, self-administered, single-dose oral therapy (i.e., the "pill-in-the-pocket" strategy) has been shown effective. Specifically, 120 mg of oral diltiazem coupled with 80 mg of oral propranolol has been shown to be superior to single-dose flecainide in terminating PSVT, decreasing the need to visit the emergency department for treatment.[63] Nonetheless, *all* forms of drug treatment designed to prevent or terminate the arrhythmia by self-administered therapy should probably be avoided in most patients because of the superior efficacy of nonpharmacologic treatment strategies.

Transcutaneous catheter ablation using radiofrequency current on the PSVT substrate has dramatically altered the traditional treatment of these patients (Fig. 25–10). 5 Radiofrequency energy delivered through a transvenous or arterial catheter causes small, discrete lesions through thermal energy. During invasive electrophysiologic studies, portions of the reentrant circuit can be located (or mapped) by the use of a number of catheters. Once this is completed, radiofrequency energy is applied, creating thermal injury in the tissue necessary for reentry. In this way, the substrate for reentry is destroyed, "curing" the patient of recurrent episodes of PSVT and obviating the need for chronic drug therapy. Historically, ablation procedures were reserved for drug-refractory patients because they necessitated open-heart surgery. However, breakthroughs in technology initially included transvenous catheter approaches, followed by the use of radiofrequency (rather than direct current) energy. Complications, although unusual, include tamponade, pericarditis, valvular insufficiency, and AV block. Radiofrequency ablation is highly effective, preventing the recurrences of PSVT in 85% to 98% of patients.[64,65] The procedure was originally used in patients with WPW syndrome.[64] In these patients, the extranodal pathway is most often located at the left lateral free wall of the left ventricle (Fig. 25–10). After the pathway is located, the catheter is put as close to the site as possible, and radiofrequency current is applied to make small burns in the tissue. Ablation of the extranodal connection occurs promptly, and evidence of preexcitation (delta waves) disappears. Thereafter, a similar approach was developed for patients with AV nodal reentry, placing the catheter in the coronary sinus, proximal to the AV node.[65] The preferred method in these individuals is to apply small amounts of radiofrequency current to the slow pathway of the reentrant circuit in order to modify its properties enough so that PSVT cannot recur.

It has been suggested that *all* patients with symptomatic PSVT undergo radiofrequency catheter ablation.[66] This is because the procedure is highly effective and curative, rarely results in complications, and obviates the need for chronic AAD therapy. In other words, radiofrequency catheter ablation should be considered in *any* patient who would previously be considered for chronic AAD treatment. Radiofrequency ablation is also a cost-effective approach (in the long term) because, if effective, the costs of drugs and repeated hospital visits are avoided. In one cost-effectiveness analysis, radiofrequency ablation improved quality of life and reduced lifetime medical expenditures by nearly $30,000 compared with chronic drug treatment.[67]

AUTOMATIC ATRIAL TACHYCARDIAS

Automatic atrial tachycardias, such as multifocal atrial tachycardia, appear to arise from supraventricular foci that have enhanced automatic properties.[68] It is presumed that multifocal atrial

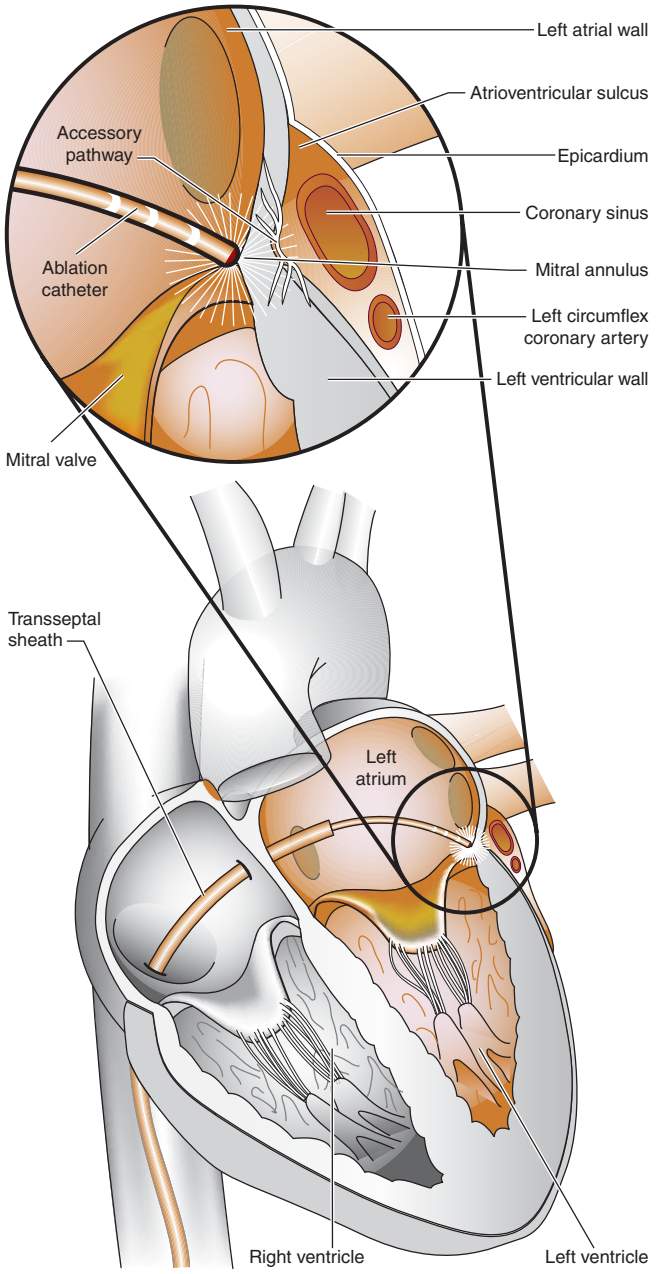

FIGURE 25-10. Drawing showing catheter placement for radiofrequency ablation of a left lateral free wall accessory pathway. Here, a venous (atrial) transseptal puncture to gain access to the Kent bundle is shown; a retrograde arterial approach has also been used. *(Lerman BB, Basson CT. High risk patients with ventricular preexcitation: A pendulum in motion. N Engl J Med 2003;349:1787–1789. Copyright © 2003 Massachusetts Medical Society. All rights reserved.)*

tachycardia is the result of multiple ectopic atrial pacemakers, which account for the variable P-wave morphologies. In unifocal atrial tachycardia (more often referred to as ectopic atrial tachycardia), a single P-wave morphology, different from that of SR, is recorded. In either case, the underlying, precipitating disorder present in the majority (60% to 80%) of these patients is severe pulmonary disease. Other disease states associated with these arrhythmias include acute infection (pneumonia and sepsis) and dilated cardiomyopathy. It should be noted that young patients without associated precipitating factors might rarely present with rapid atrial tachycardias from unknown etiologies. In these cases, long-standing tachycardias cause the cardiomyopathic state. Effective treatment of the tachycardia may result in reversal of the LV dysfunction. Traditionally, many factors (i.e., electrolyte disturbances, hypoxia, catecholamines, and tissue stretch) may cause an elevated slope of phase 4 depolarization and theoretically result in abnormal heightened automaticity. It is noteworthy that many of these factors are often clinically present in patients with concurrent pulmonary disease and automatic atrial tachycardia. However, it appears that triggered activity (i.e., LADs) is a more likely mechanism in the genesis of these tachycardias. Atrial tachycardias with AV block or a slow ventricular response should alert the clinician to the possibility of digoxin toxicity.

The first step in the treatment of automatic atrial tachycardias is to correct the underlying, precipitating factors.[68] One should ensure proper oxygenation and ventilation and correct acid–base or electrolyte disturbances. These measures alone may result in the return of SR, but in some cases, the tachycardia will persist. Patients with an asymptomatic atrial tachycardia and a relatively slow ventricular rate usually require no drug therapy. In symptomatic patients, medical therapy can be tailored either to control ventricular rate or to restore SR. Class I AADs, such as procainamide and quinidine, are only occasionally effective in restoring SR and are usually not considered first-line therapy. DCC is also ineffective in restoring SR. The use of IV β-blockers to slow ventricular rate is usually contraindicated because of the frequent coexistence of bronchospastic pulmonary disease or decompensated HF. Digoxin has been used but is controversial because of its ability to increase the automatic properties of atrial tissue, and the high sympathetic state of these patients frequently overrides the vagotonic effects of digoxin, rendering it ineffective. Non-DHP CCBs, such as verapamil, are most effective and are now considered first-line drug therapy.[52,69] Interestingly, verapamil seems to decrease ventricular rate by altering atrial automaticity, not by slowing AV nodal conduction.[69]

VENTRICULAR ARRHYTHMIAS

The common ventricular arrhythmias include (a) PVCs, (b) VT, and (c) VF. These arrhythmias may result in a wide variety of symptoms. PVCs often cause no symptoms or only mild palpitations. VT may be a life-threatening situation associated with hemodynamic collapse or may be totally asymptomatic. VF, by definition, is an acute medical emergency necessitating CPR.

CLINICAL PRESENTATION: VENTRICULAR ARRHYTHMIAS

Premature Ventricular Contractions

- PVCs are non-life-threatening and usually asymptomatic. Occasionally, patients will complain of palpitations or uncomfortable heartbeats. Since the PVC, by definition, occurs early and the ventricle contracts when it is incompletely filled, patients do not feel the PVC. Rather, the next beat (after the PVC and a compensatory pause) is usually responsible for the patient's symptoms.

Ventricular Tachycardia

- The symptoms of VT (monomorphic VT or TdP), if prolonged (i.e., sustained), can vary from nearly completely asymptomatic to pulseless, hemodynamic collapse. Fast heart rates and underlying poor LV function will result in more severe symptoms. Symptoms of nonsustained, self-terminating VT also correlate with duration of episodes (e.g., patients with 15-second episodes will be more symptomatic than those with three-beat episodes).

Ventricular Fibrillation

- By definition, VF results in hemodynamic collapse, syncope, and cardiac arrest. Cardiac output and blood pressure are not recordable.

PREMATURE VENTRICULAR COMPLEXES AND PREVENTION OF SUDDEN CARDIAC DEATH

PVCs are very common ventricular rhythm disturbances that occur in patients with or without SHD. Experimental models show that PVCs may be elicited by abnormal automaticity, triggered activity, or reentrant mechanisms. It is well known that PVCs are commonly observed in apparently healthy individuals; in these patients, the PVCs seem to have little if any prognostic significance. PVCs occur more frequently and in more complex forms in patients with SHD than in healthy individuals. The prognostic meaning of PVCs has been well studied in patients with MI (acute or remote) with several consistent themes. Patients with some forms of PVCs are at higher risk for sudden death than if they did not have these minor rhythm disturbances. SCD can be defined as unexpected death occurring in a patient within 1 hour of experiencing symptoms. Studies of patients who experienced SCD (and happened to be wearing an electrocardiographic monitor at the time) often demonstrate the cause to be VF preceded by a short run of VT and frequent PVCs.[70]

Significance

Historically, investigators promoted the concept that patients in the acute phase of MI may have types of PVCs that are predictive of VF and SCD. These types of PVCs were referred to as "warning arrhythmias" and included frequent ventricular ectopy (more than 5 beats/min), multiform configuration (different morphology), couplets (two in a row), and R-on-T phenomenon (PVCs occurring during the repolarization phase of the preceding sinus beat in the vulnerable period of ventricular recovery). However, as a result of using continuous electrocardiographic monitoring techniques, it has become apparent that almost all patients have warning arrhythmias in the acute MI setting. In those patients who experience VF, warning arrhythmias are no more common than in those without VF. Consequently, warning arrhythmias observed during acute MI are neither sensitive nor specific for determining which patients will have VF. Thus there is little need to direct drug therapy specifically at PVC suppression in these particular patients. Studies show that effective prevention of VF in the acute MI setting may be achieved without the abolition of PVCs.

Conversely, data strongly imply that PVCs documented in the convalescence period of MI do carry important long-term prognostic significance.[71] PVCs occurring after an MI seem to be a risk factor for patient death that is independent of the degree of LV dysfunction or the extent of coronary atherosclerosis. Ruberman et al.[71] employed a simple classification of PVCs: simple or benign (infrequent and monomorphic) versus "complex" (≥5 PVCs/min, couplets, R-on-T beats, and multiform). These investigators found that the presence of complex (but not simple) ventricular ectopy in the setting of CAD was associated with a higher incidence of overall mortality and cardiac death. One can see that within the controversy of the significance of PVCs is a basic question: Are complex forms of PVCs simply an unimportant marker of underlying SHD or are PVCs an important electrical disorder that should be addressed independently?

Because PVCs without associated SHD, in apparently healthy individuals, carry little or no risk, drug therapy is unnecessary. However, because of the prognostic significance of complex PVCs in patients with SHD, the use of AAD therapy to suppress them has been controversial. Historically, many supported the aggressive use of AAD therapy to suppress PVCs, based on the underlying premise of eliminating a risk factor for SCD in patients with CAD (namely the presence of complex PVCs). However, others favored a more conservative approach and disregarded the use of AAD therapy in the absence of significant symptoms. An important study, the CAST,[38] abruptly put an end to this debate in noteworthy fashion; its results are reviewed in the following section because of its great historical significance and lingering impact.

The Cardiac Arrhythmia Suppression Trial

The CAST[38,72] was initiated by the National Institutes of Health in 1987 to determine if suppression of ventricular ectopy with encainide, flecainide, or moricizine could decrease the incidence of death from arrhythmia in patients who had suffered an MI. 7 Entrance criteria included documented MI between 6 days and 2 years prior to enrollment, and ≥6 PVCs/hour (associated with no or minimal symptoms) without runs of VT >15 beats in length. Also, patients were required to have an LVEF ≤55% if recruited within 90 days of the MI or an LVEF ≤40% if recruited ≥90 days after the MI. Patients with an LVEF <30% were randomized only to encainide or moricizine. Patients were randomized to receive AAD therapy or placebo after demonstrating PVC suppression with one of the agents.

In April 1989, a routine, preliminary review of the study by the Safety and Monitoring Board revealed alarming results, and the study was interrupted. The results showed that when compared with placebo, treatment with encainide or flecainide was associated with a significantly higher rate of total mortality and death due to arrhythmia, presumably caused by proarrhythmia (Fig. 25–11). Analysis of the moricizine arm indicated neither harm nor benefit from this therapy; therefore, only this portion of the study was allowed to continue as CAST II.[72] However, in July 1991, CAST II was also prematurely discontinued because there was a trend toward an increase in mortality in moricizine-treated patients. This increase in mortality was primarily observed during the initiation of moricizine (dose-titration phase) but not during the chronic treatment phase. The overall results of the two CASTs conclusively prove that the use of AAD therapy (beyond the general use of β-blockers) to suppress PVCs in patients after an MI does not improve survival and is most likely detrimental. These studies also put into perspective the risk associated with the use of AAD therapy and the need to carefully select only those patients who would derive a defined therapeutic benefit from this therapy.

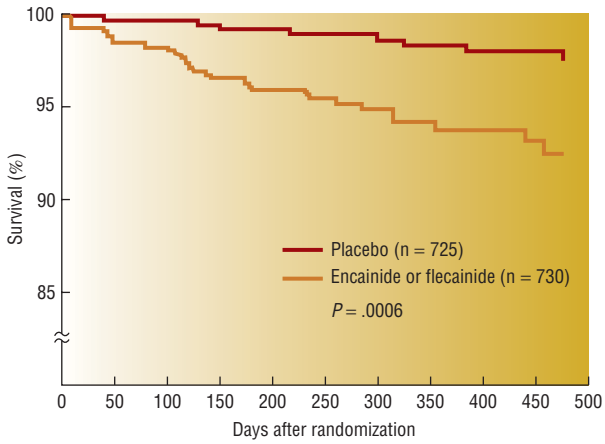

FIGURE 25-11. Life table curves from the Cardiac Arrhythmia Suppression Trial (CAST), specifically for patients receiving encainide or flecainide *(lighter line)* and matching placebo *(darker line)*. Note the divergent slopes of each line, implying a sustained risk of death (presumed proarrhythmia). *(The CAST Investigators. Preliminary report: Effect of encainide and flecainide on mortality in a randomized trial of arrhythmia suppression after myocardial infarction. N Engl J Med 1989;321:406–412. Even though the CAST was conducted more than 2 decades ago, it is considered one of the most important trials ever undertaken and has had a tremendous influence on the overall approach to the treatment of arrhythmias, as well as a far-reaching impact on AAD development. The results of the CAST have clearly had a negative influence on the long-term use of all AADs, causing a broad skepticism in the risk-versus-benefit analysis of this class of drugs. Consequently, pharmaceutical companies have shifted their drug discovery and investigative efforts away from potent sodium channel blockers. The findings of the CAST have also provided additional fuel for the pursuit of nonpharmacologic therapies for arrhythmias, such as ablation and implantable devices.

Despite the discouraging results of the CAST, post-MI patients with complex ventricular ectopy remain at risk for death. Other drugs, besides the class Ic AADs, have been studied in this patient population, including sotalol. Sotalol is marketed as a racemic mixture of a *d* and *l* isomer: both are class III potassium channel blockers but the *l* isomer has β-blocking actions. Chronic therapy with *d*-sotalol was studied in patients with a remote MI complicated by complex ectopy in the Survival With Oral *d*-Sotalol trial.[73] In this trial, *d*-sotalol treatment was not designed to cause PVC suppression (unlike the CAST), yet (like the CAST) the trial was halted prematurely because of excessive mortality in the treatment arm. Again, the presumed reason for this observation was *d*-sotalol–related proarrhythmia. Currently, only two AADs have been shown *not* to increase mortality in post-MI patients with long-term use: amiodarone and dofetilide. A number of trials[74,75] have shown amiodarone to decrease the incidence of sudden (or arrhythmic) death, but not total mortality, in post-MI patients with complex ventricular ectopy. A meta-analysis of all trials (6,553 combined patients) demonstrated a reduction in total mortality (by 13%) with long-term amiodarone therapy.[76] It is unclear if these findings can be attributed to one of amiodarone's electrophysiologic properties (e.g., β-blocking) or a combination of its complex pharmacologic effects on conduction. It is noteworthy to mention that in two major studies, patients treated with amiodarone and a β-blocker generally did better than when no β-blocker was used.[74,75] Clearly, because of its impressive side effect profile and its inability to improve survival, amiodarone should not routinely be recommended in patients with heart disease such as remote MI and complex PVCs. Two randomized, controlled trials[77,78] have also shown that chronic therapy with dofetilide has no effect on overall mortality in post-MI patients with LV dysfunction. Dofetilide (not approved for prevention of sudden death) caused TdP in approximately 5% of patients, necessitating a protocol amendment with dosage adjustments during both trials (particularly in those with renal disease because its primary route of elimination is through the kidney).

How should the clinician approach the patient with documented asymptomatic PVCs? Clearly, attempts to suppress asymptomatic PVCs should *not* be made with any AAD. Indeed, those patients who are at risk for arrhythmic death (recent MI, LV dysfunction, complex PVCs) should also *not* be routinely given *any* class I or III AAD.[79] If these patients have symptomatic PVCs, chronic drug therapy should be limited to the use of β-blockers. The use of β-blockers in post-MI patients is associated with a decrease in the incidence of total mortality and SCD, especially in the presence of LV dysfunction. These drugs can also be used in patients without underlying SHD to suppress symptomatic PVCs. 7

VENTRICULAR TACHYCARDIA

Mechanisms and Types of VT

VT is a wide QRS tachycardia that may acutely occur as a result of metabolic abnormalities, ischemia, or drug toxicity, or chronically recur as a paroxysmal form. On ECG, VT may appear as either repetitive monomorphic or polymorphic ventricular complexes. The definition of VT is three or more consecutive PVCs occurring at a rate >100 beats/min. An acute episode of VT may be precipitated by severe electrolyte abnormalities (hypokalemia or hypomagnesemia), hypoxia, or digoxin toxicity, or (most commonly) may occur during an acute MI or ischemia complicated by HF. In these cases, correction of the underlying precipitating factors will usually prevent further recurrences of VT. As an example, if VT occurs during the first 24 hours of an acute MI, it will probably not reappear on a chronic basis after the infarcted area has been reperfused or healed with scar formation. This form of acute VT may be caused by a transient reentrant mechanism within temporarily ischemic or dying ventricular tissue. In contrast, some patients have a chronic recurrent form of VT that is almost always associated with some type of underlying SHD. Common examples are paroxysmal VT associated with idiopathic dilated cardiomyopathy or remote MI with an LV aneurysm. In chronic, recurrent VT, microreentry within the distal Purkinje network is presumed to be responsible for the underlying substrate in a large majority of patients (see Fig. 25–3). Theoretically, electrophysiologic discrepancies occur as a result of structural damage and heart disease within the ventricular conducting system. The reentrant circuit may possess both anatomically determined and functional properties coursing through normal tissue, damaged (but not dead) tissue, and islands of necrosed tissue. In a minority of patients, macroreentrant circuits may be responsible for recurrent VT, including reentry incorporating the bundle branches.

Patients with acute VT associated with a precipitating factor often suffer severe symptoms, requiring immediate treatment measures. Chronic recurrent VT may also cause severe hemodynamic compromise but may also be associated with only mild symptoms that are generally well tolerated. Sustained VT is that which requires therapeutic intervention to restore a stable rhythm or persists for a relatively long time (usually >30 seconds). Nonsustained VT is that which self-terminates after a brief duration (usually <30 seconds). If the patient has VT more frequently than SR (i.e., VT is the dominant rhythm), this is referred to as incessant VT. In monomorphic VT, the QRS complexes are similar in morphologic characteristics from beat to beat. In polymorphic VT, the QRS complexes vary in shape and/or size between beats. A characteristic type of polymorphic VT, in which the QRS complexes appear to undulate around a central axis and that is associated with evidence of delayed ventricular repolarization (long QT interval or prominent U waves), is referred to as TdP.

Most but not all forms of recurrent VT occur in patients with extensive SHD. VT occurring in a patient without SHD is sometimes referred to as idiopathic VT and may take several forms.[80–82] Fascicular tachycardia arises from a fascicle of the left bundle branch (usually posterior) and is usually not associated with severe underlying SHD. In distinct contrast to the common form of recurrent VT associated with extensive SHD, non-DHP CCBs (but not adenosine) are effective in terminating an acute episode of fascicular VT. Ventricular outflow tract tachycardia (usually originating from the right ventricular outflow tract) originates from near the pulmonic valve (or uncommonly the aortic valve or LV outflow tract) and also occurs in patients with normal LV function without discernible SHD.[82] Unlike other forms of VT, right ventricular outflow tract tachycardia often terminates with adenosine and may be prevented with β-blockers and/or non-DHP CCBs.

Some unusual forms of VT are congenital or heritable (Table 25–10). TdP can be associated with heritable defects in the flux of ions that govern ventricular repolarization. Although multiple syndromes and genetic mutations have been described, the more common examples are long QT syndrome 1 (depressed I_{Ks}), long QT syndrome 2 (depressed I_{Kr}), and long QT syndrome 3

TABLE 25-10 Heritable Polymorphic Ventricular Tachycardia

Syndrome	Channel Defect	Mutant Gene	Characteristics	Treatment
$LQTS_1$	$\downarrow I_{Ks}$	KVLQT1	SCD/TdP with exercise	BB/ICD
$LQTS_2$	$\downarrow I_{Kr}$	HERG	SCD/TdP with arousal	BB/ICD
$LQTS_3$	$\uparrow I_{Na}^+$ during plateau/repolarization	SCN5A	SCD/TdP at rest/sleep	Flecainide/mexiletine/ICD
Brugada	$\downarrow I_{Na}^+$	SCN5A	SCD/PMVT or VF at rest/sleep in Asian males	ICD/quinidine

BB, β-blocker; ICD, implantable cardioverter-defibrillator; LQTS, long QT syndrome; PMVT, polymorphic ventricular tachycardia; SCD, sudden death; TdP, torsade de pointes; VF, ventricular fibrillation.
Note: LQTS can be provoked by potassium channel blockers (e.g., quinidine, sotalol), and Brugada syndrome can be provoked by potent sodium channel blockers (e.g., cocaine, flecainide). $LQTS_3$ and Brugada syndrome may coexist.

(enhanced inward sodium ion flux during repolarization).[83,84] Polymorphic VT (without a long QT interval) or VF may also occur as a result of a heritable defect in the sodium channel. This is the case in Brugada syndrome, which is described as a typical ECG pattern (ST-segment elevation in leads V_1 to V_3) in SR that is associated with SCD, and commonly occurs in males of Asian descent.[85] It is estimated that Brugada syndrome accounts for approximately 40% of all cases of VF in patients without heart disease.

Management

Consider the patient with the more common form of sustained monomorphic VT (i.e., those with SHD, usually ischemic in nature). Like other rapid tachycardias, the initial management of an acute episode of VT (with a pulse) requires a quick assessment of the patient's status and symptoms. If severe symptoms are present (i.e., severe hypotension, angina, pulmonary edema), synchronized DCC should be delivered immediately to attempt to restore SR. An investigation should be made into possible precipitating factors, and these should be corrected if possible. The diagnosis of acute MI should always be entertained. If the episode of VT is thought to be an isolated electrical event associated with a transient initiating factor (such as acute myocardial ischemia or digoxin toxicity), there is no need for long-term AAD therapy once the precipitating factors are corrected (e.g., an MI has been reperfused and healed and the patient is stable). Nevertheless, the patient should be monitored closely for possible recurrences of VT.

Patients presenting with an acute episode of VT (with a pulse) associated with only mild symptoms can be initially treated with AADs. The reader is referred to the most recent AHA guidelines for CPR and ECC.[61] IV procainamide amiodarone, or sotalol can be considered in this situation. Lidocaine can be considered as an alternative. In one small study, procainamide was shown to be superior to lidocaine in terminating VT.[86] Synchronized DCC should be delivered if the patient's status deteriorates, VT degenerates to VF (would be unsynchronized in this situation), or drug therapy fails.

Once an acute episode of sustained VT has been successfully terminated by electrical or pharmacologic means and an acute MI has been ruled out, the possibility of a patient having recurrent episodes of VT should be considered. Evidence for the possibility of VT recurrence can often be gleaned from invasive electrophysiologic studies using programmed ventricular stimulation. The management of the patient with chronic, recurrent, sustained VT deserves considerable attention. Because these patients are at extremely high risk for death, trial-and-error attempts to find effective therapy are unwarranted. To gain some objective evidence of a response to a specific AAD regimen, serial testing of these drugs using the following two surrogate end points has been used: (a) inability to induce sustained VT with programmed extrastimuli by invasive electrophysiologic studies and (b) suppression of ventricular ectopic beats by serial 24-hour continuous electrocardiographic (Holter) monitoring. These two strategies have been compared[87,88] but largely abandoned for several reasons. First, the yield for finding an effective AAD is low. For instance, sustained monomorphic VT can be rendered noninducible or nonsustained by programmed stimulation protocols in only 20% to 25% of patients. Therefore, the clinician frequently must search for other therapeutic options or settle for other treatment end points such as slower and more tolerable inducible VT. Second, amiodarone is clearly the most effective (approximately 50% effective after 2 years) AAD in patients with recurrent VT; however, electrophysiologic drug testing does not necessarily predict the clinical efficacy of amiodarone. Patients may have continued inducibility of VT on amiodarone despite long-term success. Indeed, empiric amiodarone has been compared to therapy (with other AADs) guided by electrophysiologic testing in patients at high risk for recurrent VT.[89] In this trial, amiodarone therapy without invasive testing was superior in preventing SCD and recurrences of severe ventricular arrhythmias at all time points. Third, the recurrence rate of life-threatening VT is high (20% to 50% per year depending on the AAD chosen), regardless of the method of acute drug testing. Fourth, as referred to previously, there is a substantial side-effect profile of the class I and III AADs. Lastly, and perhaps most importantly, is the impressive demonstrated effectiveness of nonpharmacologic approaches to the treatment of recurrent VT/VF.[90] For instance, some forms of recurrent VT are amenable to catheter ablation therapy using radiofrequency current. This approach is highly effective (approximately 90%) in idiopathic VT (right ventricular outflow tract or fascicular VT), but less so in recurrent VT associated with a cardiomyopathic process or remote MI with LV aneurysm. In the latter patients, ablation is usually regarded as second-line therapy after other methods have failed. Additionally, numerous trials have established the ICD as a superior treatment over AAD therapy not only for the prevention of SCD in patients who have been resuscitated from an episode of cardiac arrest or had sustained VT ("secondary prevention") but also for the prevention of an initial episode of SCD in certain high-risk patient populations ("primary prevention").

The Implantable Cardioverter-Defibrillator The introduction of and advances in the ICD (Fig. 25–12) have obviated the need to rely solely on the use of AADs to prevent episodes of life-threatening ventricular arrhythmias.[91] 8 Numerous advancements in device technology have allowed the ICD to become smaller, less invasive to implant, and programmable with advanced functions. Early ICDs required a thoracotomy to place the generator in the abdomen, whereas with the newer, smaller models, the leads are implanted transvenously with the generator placed into the pectoral region in a manner similar to cardiac pacemakers. Modern ICDs now employ a "tiered-therapy approach" meaning that overdrive pacing (i.e., antitachycardia pacing) can be

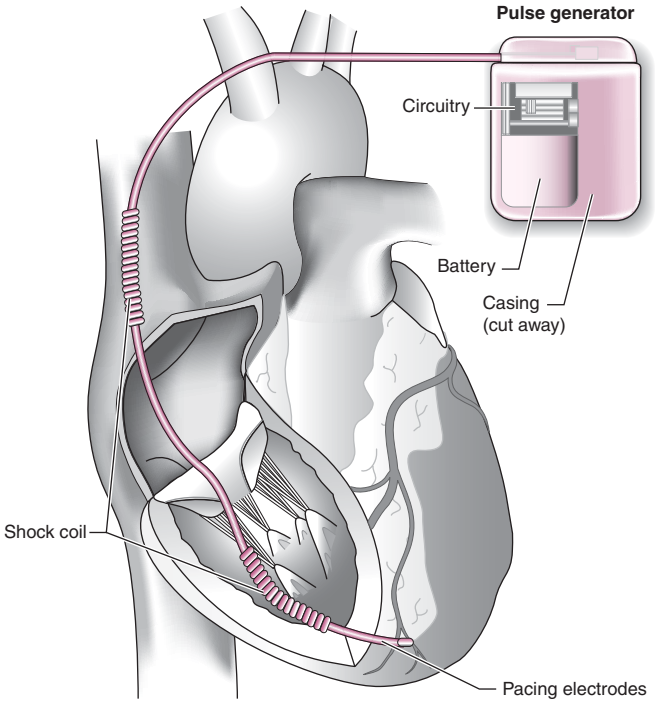

FIGURE 25-12. Drawing showing ICD. *(DiMarco JP. Implantable Cardioverter-defibrillators. N Engl J Med 2003;349:1836–1847. Copyright © 2003 Massachusetts Medical Society. All rights reserved.)*

attempted first to terminate the tachyarrhythmia (no painful shock delivered), followed by low-energy cardioversion, and, finally, by high-energy defibrillation shocks. In addition, backup antibradycardia pacing and extended battery lives have made these newer devices much more attractive. All models store recordings during delivery of pacing shocks, which is extremely important in discerning appropriate shocks (i.e., delivers shock for serious ventricular arrhythmia) from inappropriate shocks (i.e., delivers shock for AF with rapid ventricular rate) and in documenting true recurrences of the patient's tachycardia.

Although the ICD is a highly effective method for preventing SCD due to recurrent VT or VF, several problems remain. First, the device itself, the implantation procedure, electrophysiologic studies, hospitalization, and physician fees are costly. Given that the indications for receiving an ICD have significantly expanded over the past several years, the total cost associated with the implantation of this device is likely to place a great burden on the healthcare system. Second, many patients (as high as 70% of patients) with ICDs end up receiving concomitant AAD therapy (usually amiodarone or sotalol).[92,93] AADs can be initiated in these patients for a number of reasons, including (a) decreasing the frequency of VT/VF episodes to subsequently reduce the frequency of appropriate shocks; (b) reducing the rate of VT so that it can be terminated with antitachycardia pacing; and (c) decreasing episodes of concomitant supraventricular arrhythmias (e.g., AF, atrial flutter) that may trigger inappropriate shocks. As a result of these potential benefits, the concomitant use of AADs can minimize patient discomfort and prolong the battery life of the ICD. The decision to initiate concomitant AAD therapy should be individualized, with treatment usually being reserved for those with frequent shocks because of VT or AF. If AADs are added to ICD therapy, one should note that many of these drugs alter defibrillation thresholds; consequently, the device should be reprogrammed to account for this alteration.[94]

Secondary Prevention of Sudden Cardiac Death The results of three trials, the Antiarrhythmics Versus Implantable Defibrillators (AVID), Cardiac Arrest Study Hamburg (CASH), and Canadian Implantable Defibrillator Study (CIDS), definitively support the ICD as first-line therapy for the secondary prevention of SCD.[95–97] Of these, the AVID trial was the largest, randomizing more than 1,000 patients with resuscitated VF, sustained VT with syncope, or hemodynamically significant sustained VT (with LVEF ≤40%) to either an ICD or AADs (~95% receiving amiodarone at discharge).[95] The trial was stopped early because of a demonstrated superiority of the ICD; patients in the ICD group had a better overall survival when compared with those in the AAD group (75% vs. 64%, respectively, at 3 years). Although they were smaller trials, both CASH and CIDS demonstrated the efficacy of an ICD compared with amiodarone in patients with a history of sustained VT or VF, with the ICD reducing overall mortality by 20% to 25%.[96,97] Overall, the results of these three trials provide strong support for the aggressive use of the ICD in patients who are at high risk for recurrent, life-threatening ventricular arrhythmias. Implantation of an ICD can be cost-effective, particularly in patients with poor LV function. Although nearly all clinicians now consider the ICD as first-line treatment for secondary prevention of SCD, there is at least one possible patient group that may do as well with AAD therapy alone. In the AVID trial, there was no differences in survival between ICD and AAD treatment in patients with mild LV dysfunction (LVEF >35%), which suggests that long-term amiodarone therapy may be appropriate to use in this lower-risk patient population.[95] However, because these data were obtained from a post hoc analysis, additional trials are needed to confirm these findings.

Primary Prevention of Sudden Cardiac Death Over the past decade, the AVID, CASH, and CIDS trials have established the ICD as an effective treatment for the secondary prevention of SCD in patients who have previously suffered a documented episode of VT or VF. Most of the studies that have been performed in the past several years have focused on the efficacy of the ICD for primary prevention in patients deemed to be at high risk for SCD.[98–101]

One of the patient populations that appears to be at high risk for a first episode of SCD includes those with a prior MI, LV dysfunction, and nonsustained VT. The use of AADs to prevent SCD in this high-risk group has been significantly limited by the results of the CAST and other similar trials that have collectively demonstrated that these drugs may actually increase the risk of mortality in these patients. As a result of these trials, clinicians have sought a more clearly defined strategy for risk stratification in these patients before initiating drug therapy.

Traditionally, there are three strategies to approach the treatment of nonsustained VT: (a) conservative (i.e., no AAD treatment beyond β-blockers); (b) empiric amiodarone; and (c) aggressive (i.e., electrophysiologic studies with possible insertion of an ICD) (Fig. 25–13). 9 A number of early studies[102,103] suggested that tests such as electrophysiologic studies could be used to determine long-term risk in patients with nonsustained VT. For instance, Wilber et al.[102] demonstrated that post-MI patients with nonsustained VT and inducible *sustained* VT after programmed stimulation were at increased risk for subsequent VT/VF or SCD compared with those in whom sustained VT could not be induced. These data provided the basis for the Multi-center Automatic Defibrillator Implantation Trial (MADIT) and the Multicenter Unsustained Tachycardia Trial (MUSTT).[98,99] The MADIT was the first of these trials to be conducted to evaluate the efficacy of ICD therapy in this high-risk patient population. Specifically, this trial randomized patients with a previous MI, LVEF ≤36%, asymptomatic nonsustained VT, and inducible VT that was not suppressed with the use of IV procainamide to receive an ICD or conventional medical therapy (74% of patients in this particular group received amiodarone).[98] This trial was terminated prematurely after a significant survival benefit

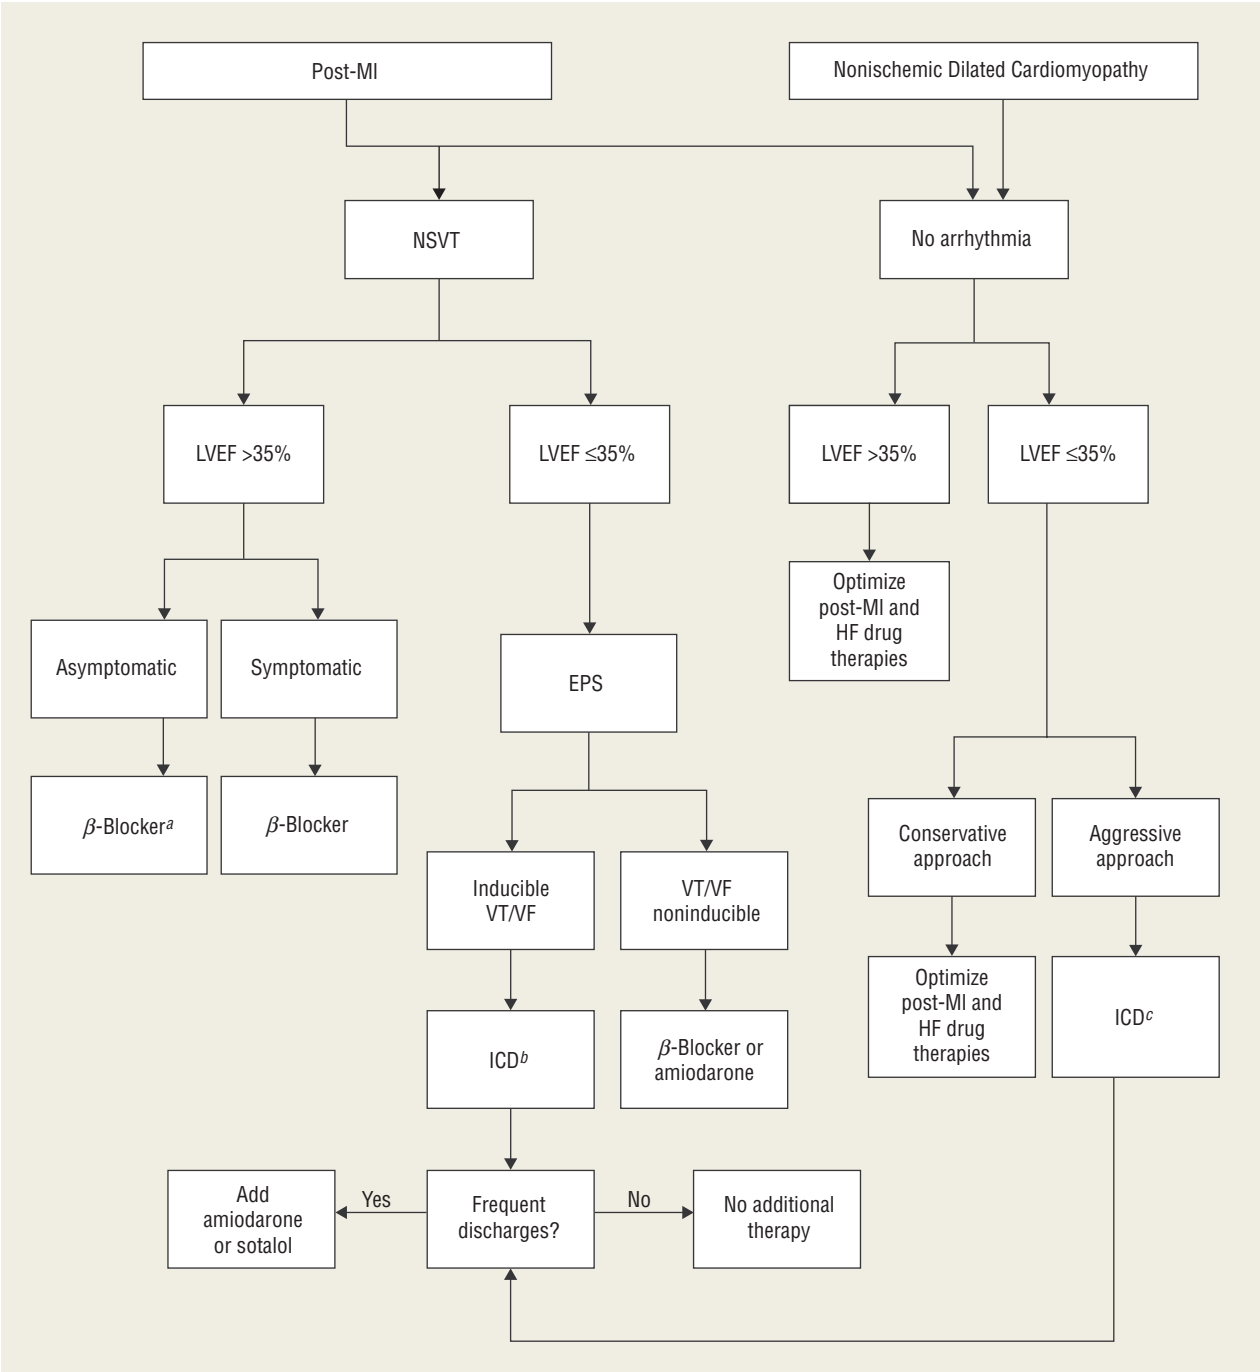

FIGURE 25-13. Algorithm for the primary prevention of SCD in patients with a history of MI or with a nonischemic dilated cardiomyopathy. [a]In these patients, the β-blocker is being used to reduce post-MI mortality. [b]Patients should be >40 days post-MI prior to insertion of the ICD. [c]Patients with an ischemic cardiomyopathy should be >40 days post-MI prior to insertion of the ICD. (EPS, electrophysiologic study; HF, heart failure; ICD, implantable cardioverter-defibrillator; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NSVT, nonsustained VT; SCD, sudden cardiac death; VF, ventricular fibrillation; VT, ventricular tachycardia.)

was detected in the ICD group. The findings of the MADIT were subsequently supported by those of the MUSTT. In the MUSTT, patients with a history of MI, LVEF ≤40%, asymptomatic nonsustained VT, and inducible sustained VT were randomized to a conservative approach (no AAD therapy beyond β-blockers) or electrophysiologically guided therapy (AADs and/or ICD).[99] The results showed that the conservative approach had a significantly higher event rate (cardiac arrest or death from arrhythmia). However, when the results of the electrophysiologically guided group were further stratified, those receiving only AADs (no ICD) were no different in terms of outcomes than those who received no treatment. In other words, only those treated with an ICD had a significantly lower event rate and greater survival. One problem with the MUSTT, however, is that, because the trial was initiated in 1989, nearly 50% of patients received class I AADs or drugs that are now known not to improve survival in patients with CAD, LV dysfunction, and ventricular arrhythmias; only 10% of patients received the most effective agent in this setting, amiodarone. Based on the results of the MADIT and MUSTT, it is reasonable for patients with CAD, LV dysfunction, and nonsustained VT to undergo electrophysiologic testing;[104] that is, invasive electrophysiologic studies with programmed stimulation are used to determine

risk and guide subsequent therapy. If these patients do not have inducible sustained VT/VF, chronic AAD therapy is unnecessary; however, if these patients do have inducible sustained VT/VF, implantation of an ICD is warranted.

Although the MADIT and MUSTT provided clinicians with important information regarding risk stratification, both of these trials targeted patients who had a history of nonsustained VT. The results of two landmark trials, the MADIT II and Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), have provided clinicians with additional information regarding the treatment of other groups of high-risk patients who have no prior history of ventricular arrhythmia (see Fig. 25–13).[100,101] In the MADIT II, patients with a prior MI and LVEF ≤30% were randomized to receive either an ICD or conventional therapy (routine post-MI and HF therapy).[100] Neither a history of ventricular arrhythmia nor electrophysiologic testing was required for inclusion in this study. Patients in the ICD group experienced a significant reduction in mortality when compared with the conventional therapy group; the reduction in mortality in the ICD group was primarily due to a reduction in arrhythmic death. Whereas the MADIT, MUSTT, and MADIT II limited enrollment to patients with ischemic cardiomyopathy, the SCD-HeFT is the largest trial, to date, to evaluate the efficacy of an ICD in a nonischemic HF population. In this trial, patients with NYHA class II or III HF (of either ischemic or nonischemic etiology) and LVEF ≤35% were randomized to receive placebo, amiodarone, or an ICD.[101] All patients were treated with appropriate HF therapies, as indicated. Implantation of an ICD resulted in a significantly lower mortality rate compared with treatment with either placebo or amiodarone (there was no difference between placebo and amiodarone). The survival benefits of the ICD were observed regardless of the etiology of the HF.

Overall, as the ICD trials have evolved over the past decade, the indications for implanting these devices have significantly expanded (Table 25–11).[105] Based on the results of the MUSTT, MADIT, MADIT II, and SCD-HeFT, many patients will be eligible for an ICD. 9 In fact, just based on the results of the MADIT II and SCD-HeFT alone, it is estimated that an additional 500,000 Medicare beneficiaries will qualify for implantation of an ICD for primary prevention of SCD.

TABLE 25-11 Current Indications for ICD Implantation

Indications	ACC/AHA/HRS Guideline Recommendation
Secondary prevention	
An ICD is *indicated* in the following individuals:	
Patients who survived an episode of cardiac arrest due to VF or have hemodynamically unstable sustained VT, not due to a reversible cause.	Class I, LOE A
Patients with structural heart disease who develop spontaneous sustained VT that is either hemodynamically stable or unstable.	Class I, LOE B
Patients with unexplained syncope who have hemodynamically unstable sustained VT or VF induced by EPS.	Class I, LOE B
An ICD is *considered reasonable* in the following individuals:	
Patients with unexplained syncope who have significant LV dysfunction and nonischemic dilated cardiomyopathy.	Class IIa, LOE C
Patients with sustained VT and normal or near-normal LV function.	Class IIa, LOE C
Primary prevention	
An ICD is *indicated* in the following individuals:	
Patients with a prior MI (occurring >40 days before ICD implantation) and LVEF ≤30% who are in NYHA FC I.	Class I, LOE A
Patients with an LVEF ≤35% due to a prior MI (occurring >40 days before ICD implantation) who are in NYHA FC II or III.	Class I, LOE A
Patients with nonsustained VT due to prior MI, an LVEF ≤40%, and inducible, sustained VT or VF at EPS.	Class I, LOE B
Patients with nonischemic dilated cardiomyopathy and an LVEF ≤35% who are in NYHA FC II or III	Class I, LOE B
An ICD is *considered reasonable* in patients who are not hospitalized and are awaiting cardiac transplantation.	Class IIa, LOE C
An ICD *may be considered* in patients with nonischemic dilated cardiomyopathy and an LVEF ≤35% who are in NYHA FC I	Class IIb, LOE C

ACC, American College of Cardiology; AHA, American Heart Association; EPS, electrophysiological study; FC, functional class; HRS, Heart Rhythm Society; ICD, implantable cardioverter-defibrillator; LV, left ventricular; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NYHA, New York Heart Association; VT, ventricular tachycardia; VF, ventricular fibrillation.

VENTRICULAR PROARRHYTHMIA

All AADs have the potential to aggravate existing arrhythmias or to cause new arrhythmias. It is believed that AADs may cause proarrhythmia in nearly 30% of patients.[10] Although drug-induced arrhythmias have been recognized for several years, only recently has this adverse effect gained widespread attention. Many definitions for proarrhythmia have been proposed; however, in the simplest terms, it indicates the development of a significant new arrhythmia (such as VT, VF, or TdP) or worsening of an existing arrhythmia (episodes are longer, faster, or more frequent). As with all arrhythmias, the consequences of proarrhythmia are varied. Some patients who develop proarrhythmia may be totally asymptomatic, others may notice a worsening of symptoms, and some may die suddenly. The development of proarrhythmia results from the same mechanisms that cause arrhythmias in general (e.g., quinidine-induced TdP due to EADs) or from an alteration in the underlying substrate due to the AAD (e.g., development of an accelerated tachycardia caused by flecainide, which decreases conduction velocity without significantly altering the refractory period) (see Fig. 25–4).[10] The diagnosis of proarrhythmia is sometimes difficult to make because of the variable nature of the underlying arrhythmias. However, in all cases, the drug should be discontinued if proarrhythmia is detected or suspected.

Incessant Monomorphic VT

The prototypical form of proarrhythmia caused by the class Ic AADs is a rapid, sustained, monomorphic VT with a characteristic sinusoidal QRS pattern that is often resistant to resuscitation with cardioversion or overdrive pacing. 10 It is sometimes referred to as sinusoidal or incessant VT and is the result of excessive sodium channel blockade and slowed conduction. Sinusoidal VT caused by the class Ic AADs was thought to occur within the first several days of drug initiation; however, the results of the CAST indicate that the risk for this type of proarrhythmia may exist as long as the drug is continued. Factors that definitely predispose a patient to this form of proarrhythmia include: (a) the presence of underlying ventricular arrhythmias; (b) CAD; and (c) LV dysfunction. Provocation of proarrhythmia by the class Ic AADs is sometimes reported during exercise, which is most likely a result of augmented slowed conduction at rapid heart rates (i.e., rate-dependent sodium blockade). The incidence of proarrhythmia caused by class Ic AADs is greatest in patients with all three risk factors (approximately 10% to 20%) and extremely uncommon in those without risks, such as patients with supraventricular tachycardias and normal LV function. In one

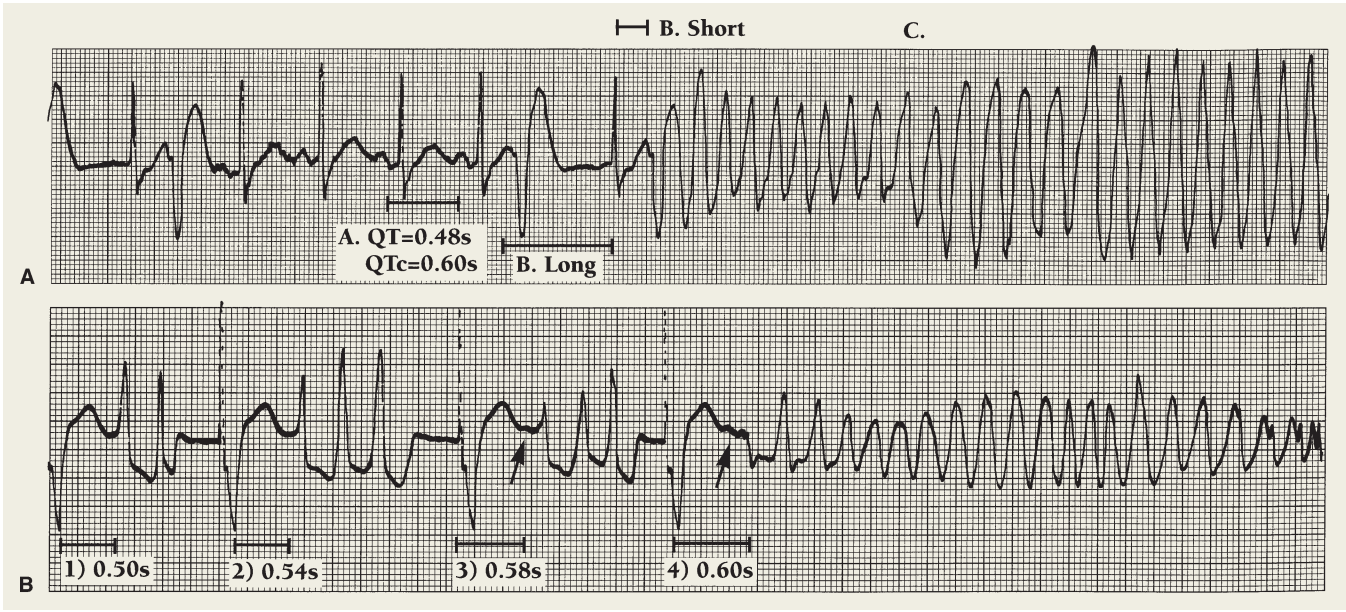

FIGURE 25-14. Torsade de pointes caused by quinidine. Note the presence of a couplet and two triplets following each extra systolic pause. The pause gets progressively longer until it is long enough to result in an episode of sustained torsade de pointes. Also, as the pause lengthens, discernible U waves (labeled ↑) (EADs?) begin to appear. The amplitude of the U wave is somewhat greater with the longest pause. *(From Bauman JL. Drug safety: Cardiac arrhythmias. Antihistamine update symposium. Hosp Med 1995;31:24, with permission.)*

study, in patients with risk factors, the incidence of death due to proarrhythmia from encainide and flecainide was approximately the same as the chance of long-term effectiveness.[106] Other factors that have a less well-defined association with proarrhythmia are elevated AAD serum concentrations and rapid dosage escalation. It has been proposed that the presence of underlying ventricular conduction delays may also pose a risk for proarrhythmia. As mentioned earlier, this arrhythmia is often resistant to resuscitation; however, some have had success with lidocaine ("fast on-off" AAD, which successfully competes with a "slow on-off" agent such as flecainide for sodium channel receptor) or sodium bicarbonate (reverses the excessive sodium channel blockade).

Torsade de Pointes

As defined previously, TdP is a rapid form of polymorphic VT (Fig. 25–14) that is associated with evidence of delayed ventricular repolarization (long QT interval or prominent U waves) on ECG. It is important to note that most forms of polymorphic VT occurring in the setting of a normal QT interval are similar to monomorphic VT in terms of etiology and treatment strategies (thus, a long QT interval is crucial to the diagnosis of TdP). Much has been learned about the underlying etiology of TdP. Basic defects (genetic, drugs, or diseases) that delay repolarization by influencing ion movement (usually by blocking potassium efflux) provoke EADs, preferentially in cells deep in the heart muscle (termed *M cells*), which, in turn, trigger reentry and TdP. Drugs that cause TdP usually delay ventricular repolarization in an inhomogeneous way (termed *dispersion of refractoriness*), which facilitates the formation of multiple reentrant loops in the ventricle.[107] TdP may occur in association with hereditary syndromes or as an acquired form (i.e., a result of drugs or diseases). The underlying etiology in both cases is delayed ventricular repolarization due to blockade of potassium conductance. It is possible, however, that some individuals have a partially expressed form of these congenital syndromes but never suffer TdP unless some other external factor (e.g., drugs, diseases, electrolyte disturbances, abrupt heart rate changes) further delays ventricular repolarization. Specifically, acquired forms of TdP are associated with electrolyte disturbances (hypokalemia or hypomagnesemia), subarachnoid hemorrhage, myocarditis, liquid protein diets, arsenic poisoning, severe hypothyroidism, or, most commonly, drug therapy (notably phenothiazines, antibiotics, antihistamines, antidepressants, and AADs) (Table 25–12). 10

The class Ia AADs (especially quinidine) and class III I_{Kr} blockers are most notorious for precipitating TdP; the class Ib and Ic AADs rarely, if ever, cause TdP (they do not appreciably delay repolarization). Most AADs with I_{Kr} blocking activity cause TdP in approximately 2% to 4% of patients, with the exceptions being amiodarone and dronedarone (<1%). Risk factors and associated features of drug-induced TdP have been identified and can be summarized as follows:[32,108] (a) high dosages or plasma concentrations of the offending drug ("dose-related") (except for quinidine-induced TdP, which tends to occur more frequently at low-to-therapeutic concentrations); (b) concurrent SHD (e.g., CAD, HF, and/or LV hypertrophy); (c) evidence of mild delayed repolarization (prolonged QT interval) at baseline; (d) evidence of a prolonged QT interval shortly after initiation of the offending drug; (e) concomitant electrolyte disturbances such as hypokalemia or hypomagnesemia; (f) female gender; and (g) a characteristic long–short initiating sequence (so-called "pause dependence") of the episode of TdP (see Fig. 25–14). However, none of these associations are absolute prerequisites to the development of drug-induced TdP. For instance, although TdP is usually documented early in the course of quinidine therapy, patients may develop this arrhythmia during chronic treatment.[109] The reason for quinidine's relatively unique propensity for causing TdP at relatively low dosages and concentrations requires explanation. Quinidine's ability to block I_{Kr} is clinically manifest at low concentrations; at higher concentrations, its sodium-channel blocking properties predominate. Other drugs that block I_{Kr} usually do so in a concentration-dependent fashion. The observation that most patients who suffer drug-induced TdP have evidence of mildly delayed repolarization (long QT intervals) even before they are prescribed the offending drug has stimulated a search for a potential genetically linked risk. Indeed, it appears that at least some patients with acquired drug-induced TdP appear to possess mutations of genes that encode for I_{Kr} or I_{Ks}.[108]

TABLE 25-12 Potential Causes of QT Interval Prolongation and Torsade de Pointes

Conditions
Congenital long QT syndromes
Myocarditis
Myocardial ischemia/infarction
Heart failure
Severe bradycardia (<50 beats/min)
Hypokalemia
Severe hypothermia
Hypomagnesemia
Severe starvation/liquid-protein diets
Subarachnoid hemorrhage
Drugs
Antiarrhythmic drugs
Quinidine
Procainamide (also *N*-acetylprocainamide)
Disopyramide
Amiodarone (<1%)
Dofetilide
Dronedarone (<1%)
Sotalol
Ibutilide
Psychotropics
Phenothiazines (e.g., thioridazine, chlorpromazine)
Tricyclic and tetracyclic antidepressants
Haloperidol/droperidol
Pimozide
Atypical antipsychotics (e.g., quetiapine, ziprasidone)
Toxins
Organophosphate insecticides
Arsenic
Antibiotics
Pentamidine
Macrolides (erythromycin and clarithromycin)
Trimethoprim-sulfamethoxazole
Fluoroquinolones (levofloxacin, moxifloxacin, gemifloxacin)
Voriconazole
Pain
Methadone
Miscellaneous
Liquid-protein diets[a]
Corticosteroids[a]
Diuretics[a]
Quinine
Chloroquine
Chloral hydrate
Tacrolimus

[a]More than likely a result of severe electrolyte imbalance.
Note: For a complete list, see *www.qtdrugs.org*.

The common underlying electrophysiologic cause of TdP is a delay in ventricular repolarization (provoking EADs), which usually results from inhibition (drug-induced or genetic) of I_K current and manifests as QT interval prolongation on the ECG. Therefore, the extent of QT interval prolongation has been used as a measurement of risk of TdP; however, considerable controversy exists. Amiodarone, for example, commonly causes significant QT prolongation but is a relatively infrequent cause of TdP. Nonetheless, the QT interval should be measured and monitored in all patients prescribed drugs that have a high potential for causing TdP (see Table 25–12). Patients with a baseline QT_c interval (QT interval corrected for heart rate, which can be calculated using Bazett's formula: QT_c = QT measured/$\sqrt{\text{R-R interval}}$) >450 msec should not be given drugs that have a high potential for causing TdP; an increase in the QT_c interval to ≥560 msec after the initiation of the drug is an indication to discontinue the agent or, at least, to reduce its dosage and carefully observe and monitor.

Drug-induced TdP has become an extremely visible hazard plaguing new drugs, sometimes resulting in public health disasters. For instance, several drugs (cisapride, astemizole, levomethadyl, grepafloxacin, sparfloxacin, and terfenadine) have been withdrawn from the market in the United States because of their significant potential for causing TdP. One of the most visible and striking examples was with regard to the popular nonsedating antihistamine, terfenadine. Terfenadine is a potent I_{Kr} blocker but is rapidly metabolized by CYP3A4 to an active moiety (fexofenadine) that is not associated with delayed repolarization. Consequently, in the presence of drugs that block the CYP3A4 isoenzyme (e.g., ketoconazole, erythromycin, diltiazem), accumulation of the parent compound, terfenadine, causes clinically significant blockade of I_{Kr} that could result in TdP and even death.[110] Because of experiences like this, all new drug entities under investigation are screened for their ability to block I_K and cause significant QT prolongation.

Acute treatment of TdP is different than treatment for the more common acute monomorphic VT. For an acute episode of TdP, most patients will require and respond to DCC. However, TdP tends to be paroxysmal in nature and often will rapidly recur after DCC. Therefore, after the initial restoration of a stable rhythm, therapy designed to prevent recurrences of TdP should be instituted. AADs that further prolong repolarization such as IV procainamide are absolutely contraindicated. Lidocaine is usually ineffective. Although there are no true efficacy trials, IV magnesium sulfate, by suppressing EADs, is now considered the drug of choice in preventing recurrences of TdP.[111] If IV magnesium sulfate is ineffective, treatment strategies designed to increase heart rate, shorten ventricular repolarization, and prevent the pause dependency should be initiated. Either temporary transvenous pacing (105 to 120 beats/min) or pharmacologic pacing (isoproterenol or epinephrine infusion) can be initiated for this purpose. All drugs that prolong the QT interval should be discontinued, and exacerbating factors (e.g., hypokalemia or hypomagnesemia) should be corrected.

VENTRICULAR FIBRILLATION

Background and Prevention

VF is electrical anarchy of the ventricle resulting in no cardiac output and cardiovascular collapse. Death will ensue rapidly if effective treatment measures are not taken. Patients who die abruptly (within 1 hour of initial symptoms) and unexpectedly (i.e., "sudden death") usually have VF recorded at the time of death.[112] SCD accounts for about 310,000 deaths per year in the United States.[16] SCD occurs most commonly in patients with CAD and those with LV dysfunction; it occurs less commonly in those with WPW syndrome or mitral valve prolapse, and occasionally in those without associated heart disease (e.g., Brugada syndrome). Patients who have SCD (not associated with acute MI) but survive because of appropriate CPR and defibrillation (where warranted), often have inducible sustained VT and/or VF during electrophysiologic studies. These individuals are at high risk for the recurrence of VT and/or VF.

In contrast, patients who have VF associated with acute MI (i.e., within the first 24 hours after symptoms) usually have little risk of recurrence. Of all patients who die as a result of an acute MI, approximately 50% die suddenly prior to hospitalization.

VF associated with acute MI can be subdivided into two types: primary VF and complicated or secondary VF. Primary VF occurs in an uncomplicated MI not associated with HF; secondary VF occurs in an MI complicated by HF. The time course, incidence, mechanisms, treatment, and complications of these two forms of VF are different. For example, approximately 2% to 6% of patients with acute MI suffer primary VF within 24 hours of chest pain, but the risk of VF declines rapidly over time and is nearly zero after the initial 24-hour period. Complicated or secondary VF does not follow such a predictable time course and may occur in the late infarction period. The premise of prophylactic AADs administered to all patients with uncomplicated MI is based on (a) the inability to predict which patients are at risk for primary VF and (b) the predictable time course of primary VF (in contrast to complicated VF). Of the prophylactic therapies used, lidocaine has been the most widely debated and studied. Lie et al.[113] performed the classic study showing the effectiveness of lidocaine in preventing primary VF. Although lidocaine significantly reduced the incidence of VF compared with placebo, there was no significant difference in mortality due to VF between the groups. These results, along with the effectiveness of rapidly instituted defibrillation in modern coronary care units with sophisticated monitoring techniques, have caused most to reject the notion of prophylactic lidocaine administration for all patients with uncomplicated MI. In support of this, two meta-analyses[114,115] concluded against the routine use of prophylactic lidocaine because of a possible increase in mortality in lidocaine-treated patients[114] as well as the declining incidence of primary VF documented in recent years (probably a result of the more aggressive and rapid use of β-blockers, thrombolytics, and percutaneous intervention for the treatment of acute coronary syndromes).[115]

The use of IV magnesium sulfate has also been entertained for the prevention of VF during the acute infarction period. Small trials implying its effectiveness were subsequently incorporated into a meta-analysis.[116] This meta-analysis found a decrease in the incidence of VT/VF and a reduction in total mortality with IV magnesium therapy. A subsequent large multicenter trial[117] found similar results, although most of the reduction in mortality with IV magnesium was (surprisingly) attributed to HF deaths rather than to deaths caused by ventricular arrhythmia. These results would lead one to conclude that magnesium sulfate should be routinely administered to patients with suspected MI because of its ease of administration and safety. However, data from another large trial apparently have verified no such effectiveness of magnesium therapy in this setting.[118] Hence, prophylactic magnesium cannot be recommended for this purpose. In addition, AADs have not shown any conclusive benefit in preventing VF in the acute infarction period; as such, these drugs also cannot be recommended in this setting.

Acute Management

A patient with pulseless VT or VF should be managed according to the most recent AHA guidelines for CPR and ECC.[61] A detailed discussion regarding the acute management of pulseless VT/VF can be found in Chapter 18 (Cardiopulmonary Resuscitation).

BRADYARRHYTHMIAS

SINUS NODE DYSFUNCTION

The previous sections reviewed the pathophysiology and treatment of tachyarrhythmias, and this section serves to briefly consider the bradyarrhythmias. For the most part, the symptoms of bradyarrhythmias result from a decline in cardiac output. Because cardiac output decreases as heart rate decreases (to a point), patients with bradyarrhythmias may experience symptoms in association with hypotension, such as dizziness, syncope, fatigue, and confusion. If LV dysfunction exists, patients may experience worsening HF symptoms. Except in the case of recurrent syncope, symptoms associated with bradyarrhythmias are often subtle and nonspecific.

SINUS BRADYCARDIA

Sinus bradyarrhythmias (heart rate <60 beats/min) are a common finding, especially in young, athletically active individuals, and usually are neither symptomatic nor in need of therapeutic intervention. On the other hand, some patients, particularly the elderly, have sinus node dysfunction. This may be the result of underlying SHD and the normal aging process that attenuate SA nodal function over time. Sick sinus syndrome refers to this process resulting in symptomatic sinus bradycardia and/or periods of sinus arrest.[119,120] Sinus node dysfunction is usually reflective of diffuse conduction disease, and accompanying AV block is relatively common. Furthermore, symptomatic bradyarrhythmias may be accompanied by alternating periods of paroxysmal tachycardias such as AF. In this instance, AF sometimes presents with a rather slow ventricular response (in the absence of AV nodal blocking drugs) because of diffuse conduction disease. The occurrence of alternating bradyarrhythmias and tachyarrhythmias is referred to as the tachy-brady syndrome. The occurrence of paroxysmal AF in a patient with sinus node dysfunction may be a result of underlying SHD with atrial dysfunction or atrial escape in response to reduced sinus node automaticity. In fact, because the rate of impulse generation by the sinus node is generally depressed or may fail altogether, other automatic pacemakers within the conduction system may "rescue" the sinus node. These rescue rhythms often present as paroxysmal atrial rhythms (e.g., AF) or as a junctional escape rhythm.

The treatment of sinus node dysfunction involves the elimination of symptomatic bradycardia and potentially managing alternating tachycardias such as AF. In general, the long-term therapy of choice is a permanent ventricular pacemaker. Dual-chamber, rate-adaptive chronic pacing clearly improves symptoms and overall quality of life and decreases the incidence of paroxysmal AF and systemic embolism.[119] Drugs commonly employed to treat supraventricular tachycardias should be used with caution, if at all, in the absence of a functioning pacemaker. AADs prescribed to prevent AF recurrences may also suppress the escape or rescue rhythms that appear in severe sinus bradycardia or sinus arrest. Consequently, these drugs may transform an asymptomatic patient with bradycardia into a symptomatic one. The addition of class I AADs can also affect pacemaker threshold and result in loss of capture if the pacemaker is not appropriately interrogated and adjusted. Other drugs that depress SA or AV nodal function, such as β-blockers and non-DHP CCBs, may also significantly exacerbate bradycardia. Even drugs with indirect sympatholytic actions, such as methyldopa and clonidine, may worsen sinus node dysfunction. The use of digoxin in these patients is controversial; however, in most cases, it can be used safely.

Other Causes

Another reason for paroxysmal bradycardia and sinus arrest that is not directly due to sinus node dysfunction is carotid-sinus hypersensitivity.[121,122] Again, this syndrome occurs commonly in the elderly with underlying SHD, and may precipitate falls and hip fractures. Symptoms occur when the carotid sinus is stimulated, resulting in an accentuated baroreceptor reflex. Often, however, symptoms are not well correlated with the obvious physical manipulation of the carotid sinus (in the lateral neck region). Patients may experience intermittent episodes of dizziness or syncope because of sinus arrest caused by increased vagal tone and sympathetic withdrawal (the cardioinhibitory type), a drop in systemic blood pressure caused by sympathetic

withdrawal (the vasodepressor type), or both (mixed cardioinhibitory and vasodepressor types). The diagnosis can be confirmed by performing carotid-sinus massage with ECG and blood pressure monitoring in controlled conditions. Symptomatic carotid-sinus hypersensitivity should also be treated with permanent pacemaker therapy.[121] However, some patients, particularly those with a significant vasodepressor component, still experience syncope or dizziness. The choice of definitive drug therapy in this situation is marred by the lack of controlled trials, although α-adrenergic stimulants such as midodrine are often tried in addition to the pacemaker.[122]

Vasovagal syndrome, by causing bradycardia, sinus arrest, and/or hypotension, is the cause of syncope in many patients who present with recurrent fainting of unknown origin.[123–125] By history, many individuals can recount rare instances of fainting spells at times of duress or fear. These are most often caused by vasovagal syncope. However, some have extremely frequent, unexpected syncopal episodes that interfere with the patient's quality of life and cause physical danger (sometimes referred to as neurocardiogenic syncope syndrome or malignant vasovagal syndrome). Vasovagal syncope is presumed to be a neurally mediated, paradoxical reaction involving stimulation of cardiac mechanoreceptors (i.e., Bezold-Jarisch reflex). Forceful contraction of the ventricle (e.g., as with adrenergic stimulation) coupled with low ventricular volumes (e.g., with upright posture or dehydration) provides a powerful stimulus for cardiac mechanoreceptors. Syncope results from the spontaneous development of transient hypotension (sympathetic withdrawal) and bradycardia (vagotonia). However, the true mechanism of vasovagal syncope remains to be definitively determined. For instance, patients with denervated hearts (e.g., heart transplant recipients) can still experience this form of syncope. This observation has led some to question the ultimate role of the Bezold-Jarisch reflex in these patients. Regardless, patients believed to have frequent episodes of vasovagal syncope have been evaluated and diagnosed using the upright body-tilt test,[126] a potent stimulus for the development of vasovagal symptoms. Although commonly used, the sensitivity and reproducibility of this test have been questioned.[127]

Traditionally, β-blockers, such as metoprolol, were frequently chosen as the drugs of choice in preventing episodes of vasovagal syncope. Although these drugs may seem inappropriate to treat a syndrome resulting from vasodilation and bradycardia, the therapeutic approach is designed to block an inappropriate vasovagal reaction (i.e., they inhibit the sympathetic surge that causes forceful ventricular contraction and precedes the onset of hypotension and bradycardia). To most clinicians' surprise, most controlled trials of the use of β-blockers in patients with severe vasovagal syncope have shown no effect compared with placebo in preventing syncopal episodes.[128] Some trials have suggested that β-blockers are more effective and should be used in older patients (>40 years of age) with vasovagal syncope rather than the relatively young.[129] Other drugs that have been used successfully (with or without β-blockers) include mineralocorticoids as volume expanders (fludrocortisone), anticholinergic drugs (scopolamine patches, disopyramide), α-adrenergic agonists (midodrine), adenosine analogs (theophylline, dipyridamole), and selective serotonin receptor antagonists (sertraline, paroxetine).[130] Permanent pacing has been used with some success but should be reserved for drug-refractory patients.[124,125] Because of the questionable effectiveness of β-blockers and the paucity of controlled or comparative trials, there is not a true drug of choice for severe vasovagal syncope, and clinicians are left with choosing agents and judging clinical effectiveness in individual patients on a case-by-case basis.

ATRIOVENTRICULAR BLOCK

Conduction delay or block may occur in any area of the AV conduction system: the AV node, the His bundle, or the bundle branches.

TABLE 25-13 Forms of Atrioventricular Block

Type	Criteria	Site of Block
First-degree block	Prolonged PR interval (>0.2 s); 1:1 AV conduction	Usually AVN
Second-degree block		
Mobitz I	Progressive PR prolongation until QRS is dropped; <1:1 AV conduction	AVN
Mobitz II	Random nonconducted beats (absence of QRS); <1:1 AV conduction	Below AVN
Third-degree block	AV dissociation; absence of AV conduction	AVN or below

AV, atrioventricular; AVN, atrioventricular node.

AV block is usually categorized into three different types based on ECG findings (Table 25–13). First-degree AV block is 1:1 AV conduction with a prolonged PR interval. Second-degree AV block is divided into two forms: Mobitz I AV block (Wenckebach periodicity) is less than 1:1 AV conduction with progressively lengthening PR intervals until a ventricular complex is dropped; Mobitz II AV block is intermittently dropped ventricular beats in a random fashion without progressive PR lengthening. Third-degree AV block is complete heart block where AV conduction is totally absent (AV dissociation). By using intracardiac His bundle ECGs, the actual site of conduction delay/block can be determined and correlated to the type of AV block. First-degree AV block usually represents prolonged conduction in the AV node. Mobitz I, second-degree AV block is also usually caused by prolonged conduction in the AV node. Indeed, Wenckebach periodicity is a normal AV nodal response to rapid supraventricular stimulation or high vagal tone. In contrast, Mobitz II, second-degree AV block is usually caused by conduction disease below the AV node (i.e., His bundle). Third-degree AV block may be caused by disease at any level of the AV conduction system: complete AV nodal block, His bundle block, or trifascicular block. In this situation, the ventricle beats independently of the atria (AV dissociation), and the rate of ventricular activation and QRS configuration are determined by the site of the AV block. The usual degree of automaticity of ventricular pacemakers progressively declines as the site of impulse generation moves down the ventricular conduction system. Therefore, the ventricular escape rate in cases of trifascicular block will be significantly less than complete AV nodal block. Consequently, trifascicular block is a much more dangerous form of AV block. For instance, complete AV block at the level of the AV node usually results in the ventricular rhythm being controlled by the stable AV junctional pacemaker (rate ~40 beats/min). In contrast, in complete AV block due to trifascicular or His bundle block, a much less reliable pacemaker with slower rates below the site of block controls ventricular rhythm.

AV block may be found in patients without underlying SHD such as trained athletes or during sleep when vagal tone is high. Also, AV block may be transient where the underlying etiology is reversible such as in myocarditis, myocardial ischemia, after cardiovascular surgery, or during drug therapy. β-blockers, digoxin, or non-DHP CCBs may cause AV block, primarily in the AV nodal area. Class I AADs may exacerbate conduction delays below the level of the AV node (sodium-dependent tissue). In other cases, AV block may be irreversible, such as that caused by acute MI, rare degenerative diseases, primary myocardial disease, or congenital heart disease.

If patients with Mobitz II AV block or third-degree AV block develop signs or symptoms of poor perfusion (e.g., altered mental status, chest pain, hypotension, shock), IV atropine (0.5 mg given

every 3 to 5 minutes, up to 3 mg total dose) should be administered.[61] If these patients do not respond to atropine, transcutaneous pacing can be initiated. Sympathomimetic infusions such as epinephrine (2 to 10 mcg/min) or dopamine (2 to 10 mcg/kg/min) can also be used in the event of atropine failure and are particularly effective in sinus bradycardia/arrest and AV nodal block. An isoproterenol infusion (2 to 10 mcg/min) may be considered if the patient does not respond to dopamine or epinephrine however, this drug should be used with caution because of its vasodilating properties and ability to increase myocardial oxygen consumption (particularly during active MI). As would be expected, these drugs usually do not help when the site of AV block is below the AV node (e.g., Mobitz II or trifascicular AV block) because their primary mechanism is to accelerate conduction through the AV node. If patients with bradycardia or AV block present with signs and symptoms of adequate perfusion, no acute therapy other than close observation is recommended.

Patients with chronic symptomatic AV block should be treated with the insertion of a permanent pacemaker. Patients without symptoms can sometimes be followed closely without the need for a pacemaker. The reader is referred for more detail to the national consensus guidelines for pacemaker implantation, which were last updated in 2008.[105] Patients with acute MI and evidence of new AV block or conduction disturbances will often require the insertion of a temporary transvenous pacemaker. AV block more commonly occurs as a complication of inferior wall MIs because of high vagal innervation at this site, and the coronary blood flow to the nodal areas usually supplies the inferior wall. However, the AV block may only be transient, obviating the need for permanent pacing. In patients with chronic AV conduction disturbances, intracardiac recordings (His bundle ECGs) are sometimes used to document the actual site of block and define the potential need for and specific type of pacemaker therapy.

EVALUATION OF THERAPEUTIC AND ECONOMIC OUTCOMES

Generally, patients who suffer from tachyarrhythmias can be monitored for one or several possible therapeutic outcomes. Obviously, the presence or recurrence of any arrhythmia can be documented by electrocardiographic means (e.g., surface ECG, Holter monitor, or event monitor). Furthermore, patients may experience a decrease in blood pressure that may result in symptoms ranging from lightheadedness to abrupt syncope, depending on the rate of the arrhythmia and the status of the underlying heart disease. For some patients, the potential alteration in hemodynamics may result in death if the arrhythmia is not detected and treated immediately. Besides these clinical outcomes, many patients with tachyarrhythmias experience alterations in quality of life as a result of recurrent symptoms of the arrhythmia or from side effects of therapy. And, finally, there are the economic considerations of medical or surgical intervention, continued medical care, and chronic drug or nonpharmacologic treatment.[131,132] Most of the studies are limited to the use of nonpharmacologic therapies such as the ICD or radiofrequency ablation.[50,104] Because that technology is rapidly evolving, what is not very cost-effective now may indeed be cost-effective in the next several years. For example, original cost-effectiveness analysis of the ICD showed it to be highly sensitive to the life of the generator, yet newer-generation devices have made significant advances not only in the size but also in battery life. More recent data on the effect of the ICD on mortality coupled with the declining costs of an ICD imply that the device is indeed cost-effective in certain subsets of patients, which is similar to well-proven drug therapies used for other disorders.[104,133] Other nonpharmacologic treatments, such as radiofrequency ablation, for PSVT not only improve quality of life but also save money on medical expenditures compared with chronic drug therapy.[52]

TABLE 25-14 Arrhythmia Outcomes

Mortality
Total, all-cause
Arrhythmic death (i.e., sudden cardiac death)
Recurrences documented by electrocardiogram
Time to recurrence
Frequency of recurrences
Tolerance
Symptoms
Blood pressure
Rate of tachycardia
Surrogate markers of efficacy such as:
Number of premature ventricular complexes/day
Inducibility of tachycardia with programmed stimulation
Necessity of nondrug interventions (e.g., ICD)
ICD shocks
Side effects of drugs/treatment complications
Quality of life
Economics
Outcomes specific to tachycardia (e.g., systemic embolism in atrial fibrillation)

ICD, implantable cardioverter-defibrillator.

There are some therapeutic outcomes that are unique to certain arrhythmias. For instance, patients with AF or atrial flutter need to be monitored for thromboembolism and for complications of antithrombotic therapy (bleeding, drug interactions). However, the most important monitoring parameters for most patients fall into the following categories: (a) mortality (total and arrhythmic); (b) arrhythmia recurrence (duration, frequency, symptoms); (c) hemodynamic consequences (heart rate, blood pressure, symptoms); and (d) treatment complications (side effects or need for alternative or additional drugs, devices, surgery) (Table 25–14). When evaluating the arrhythmia literature, care should be taken to consider real outcomes. For example, total mortality is more meaningful than only SCD rates; it is possible an intervention prevents arrhythmic death but patients die from other causes, leaving all-cause mortality unaltered. Likewise, surrogate markers of drug efficacy (e.g., noninducible tachycardia, suppression of minor arrhythmias) should be judged with a degree of skepticism. One should ask: Did the treatment make patients live longer (reduce mortality)? Did the treatment make them feel better (improve humanistic outcomes or quality of life)? Was the treatment economically worth it (cost-effective)?

ABBREVIATIONS

AAD: antiarrhythmic drug

ACC: American College of Cardiology

ACCP: American College of Chest Physicians

ACTIVE: Atrial Fibrillation Clopidogrel Trial with Irbesartan for Prevention of Vascular Events

AF: atrial fibrillation

AFFIRM: Atrial Fibrillation Follow-up Investigation of Rhythm Management trial

AHA: American Heart Association

AV: atrioventricular

AVID: Antiarrhythmics Versus Implantable Defibrillators trial

CAD: coronary artery disease

CASH: Cardiac Arrest Study Hamburg
CAST: Cardiac Arrhythmia Suppression Trial
CCB: calcium channel blocker
CIDS: Canadian Implantable Defibrillator Study
CPR: cardiopulmonary resuscitation
CYP: cytochrome P450
DCC: direct-current cardioversion
DHP: dihydropyridine
EAD: early after-depolarization
ECC: emergency cardiovascular care
ECG: electrocardiogram
ESC: European Society of Cardiology
HF: heart failure
HOT-CAFE: How to Treat Chronic Atrial Fibrillation trial
ICD: implantable cardioverter-defibrillator
INR: international normalized ratio
IV: intravenous
LAD: late after-depolarization
LV: left ventricular
LVEF: left ventricular ejection fraction
MADIT: Multicenter Automatic Defibrillator Implantation Trial
MI: myocardial infarction
MUSTT: Multicenter Unsustained Tachycardia Trial
NYHA: New York Heart Association
PIAF: Pharmacological Intervention in Atrial Fibrillation trial
PSVT: paroxysmal supraventricular tachycardia
PVC: premature ventricular complex
RACE: Rate Control versus Electrical Cardioversion for Persistent Atrial Fibrillation trial
RMP: resting membrane potential
SA: sinoatrial
SCD: sudden cardiac death
SCD-HeFT: Sudden Cardiac Death in Heart Failure Trial
SHD: structural heart disease
SR: sinus rhythm
STAF: Strategies of Treatment of Atrial Fibrillation trial
TdP: torsade de pointes
TEE: transesophageal echocardiography
VF: ventricular fibrillation
VT: ventricular tachycardia
WPW: Wolff-Parkinson-White syndrome

CHAPTER 26

Venous Thromboembolism

DANIEL M. WITT, EDITH A. NUTESCU, AND STUART T. HAINES

KEY CONCEPTS

1. The risk of venous thromboembolism (VTE) is related to several easily identifiable factors, including age, major surgery (particularly orthopedic procedures of the lower extremities), previous VTE, trauma, malignancy, prolonged immobility or limb paralysis, and hypercoagulable states. These risks are additive.
2. The diagnosis of VTE should be confirmed by objective testing.
3. Antithrombotic therapies require meticulous and systematic monitoring as well as ongoing patient education. Well-organized anticoagulation management services improve the quality of patient care and reduce overall cost.
4. Bleeding is the most common adverse effect associated with anticoagulant drugs. A patient's risk of major hemorrhage is related to the intensity and stability of therapy, concurrent drug use, history of gastrointestinal bleeding, history of prior noncadioembolic stroke, renal or hepatic impairment, thrombocytopenia, recent surgery or trauma, and increasing age.
5. At the time of hospital admission, all patients should receive prophylaxis against venous thromboembolism that corresponds to their level of risk. Prophylaxis should be continued throughout the period of risk.
6. In the absence of contraindications, the treatment of VTE should initially include a rapid-acting anticoagulant (e.g., unfractionated heparin, low-molecular-weight heparin, or fondaparinux). If the patient is transitioned to warfarin therapy, the rapid-acting anticoagulant should be overlapped with warfarin for at least 5 days and until the patient's international normalized ratio is greater than 2.0. Anticoagulation therapy should be continued for a minimum of 3 months. The duration of anticoagulation therapy should be based on the patient's risks of VTE recurrence and major bleeding, and preference regarding continued treatment.
7. Most patients with an uncomplicated deep vein thrombosis, with or without pulmonary embolism, can be safely treated as an outpatient.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Venous thromboembolism (VTE) is a potentially fatal disorder and a significant health problem in our aging society.[1,2] Although it can strike young, otherwise healthy adults, it most frequently occurs in patients who sustain multiple trauma, undergo major surgery, are immobile for a lengthy period of time, or have a hypercoagulable disorder. Resulting from clot formation within the venous circulation (Fig. 26–1), VTE is manifested as deep vein thrombosis (DVT) and pulmonary embolism (PE). Death from PE can occur within minutes after the onset of symptoms, before effective treatment can be given.

Unfortunately, the disease is often clinically silent, and the first manifestation may be sudden death. In some case series, 80% of patients who died suddenly had some evidence of PE at the time of autopsy.[2] Beyond the symptoms produced by the acute event, the complications of VTE, such as the postthrombotic syndrome and chronic thromboembolic pulmonary hypertension (CTPH), also cause substantial disability and suffering.[1]

The treatment of VTE is fraught with substantial risks.[3] Antithrombotic drugs require precise dosing and meticulous monitoring.[4,5] Systematic approaches to drug therapy management substantially reduce the risks, but bleeding remains an all too common and serious complication of administering antithrombotic drugs. Consequently, the prevention of VTE in at-risk patients is paramount to improving outcomes.[2] When there is a suspicion of VTE, the rapid and accurate diagnosis of the disorder is critical to making appropriate treatment decisions.[6,7] The optimal use of antithrombotic drugs requires not only an in-depth knowledge of their pharmacology and pharmacokinetic properties, but also a comprehensive approach to patient management.[4,5]

EPIDEMIOLOGY

The true incidence of VTE in the general population is unknown, because a substantial portion of patients, perhaps more than 50%, have clinically silent disease. An estimated 350,00 to 600,00 people in the United States develop VTE each year and more than 100,000 die.[8] The estimated annual direct medical costs of managing the disease are well over $1 billion and growing. The estimated age-adjusted annual incidence of symptomatic VTE in whites is 100 per 100,000.[9] The incidence of VTE nearly doubles in each decade of life over the age of 50 years and is slightly higher in men. African Americans appear to be at somewhat higher risk of VTE than are Americans of predominantly European ancestry, whereas Hispanic Americans may be at slightly lower risk. Asian Americans and Pacific Islanders appear to have a strikingly low incidence of VTE. While the age-adjusted incidence of PE has declined slightly in recent years, the total number of cases of DVT and PE continues to climb as the population ages.

The incidence of VTE in specific high-risk patient populations has been extensively studied.[2] Patients who sustain multiple traumas

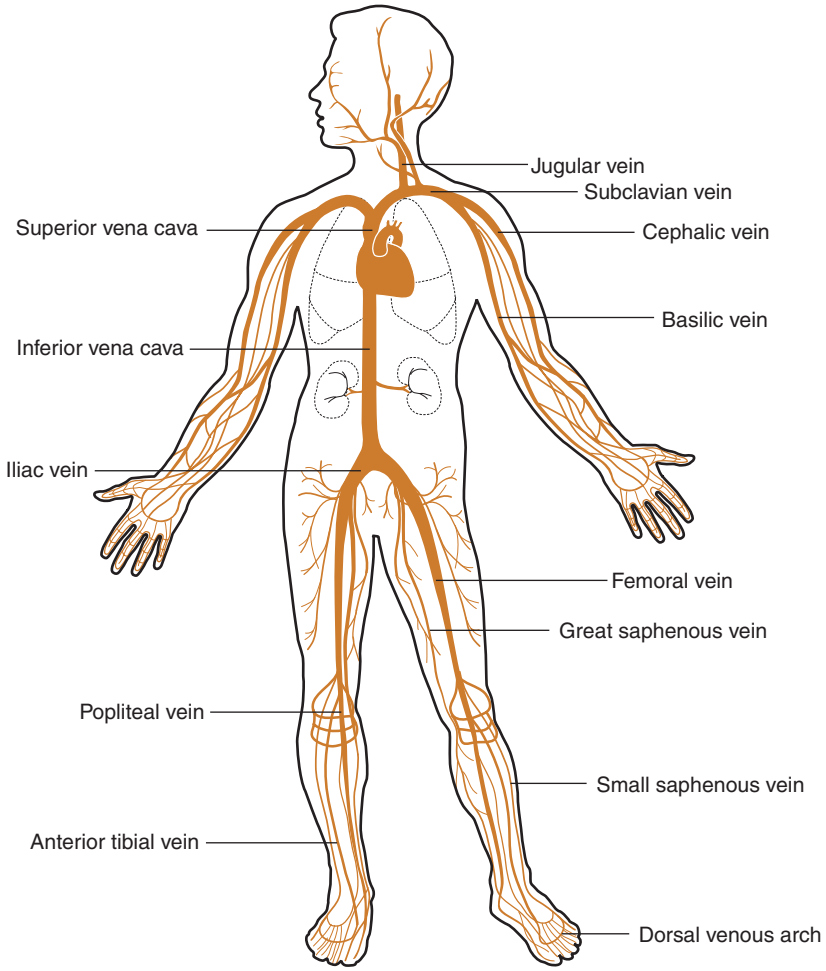

FIGURE 26-1. Venous circulation.

or undergo an orthopedic procedure involving a lower extremity are at particularly high risk, with the incidence of VTE often exceeding 50% in the absence of effective prophylaxis. Among those undergoing major surgeries other than procedures involving the lower extremities, the incidence of VTE is 20% to 40% when one or more other risk factors are present, such as age older than 60 years. The long-term incidence of VTE among patients who have a prior history of VTE and who have metastatic cancer is extremely high. Likewise, the incidence of VTE after a myocardial infarction, stroke, and spinal cord injury is high. Several disorders of hypercoagulability have also been linked to a high lifetime incidence of VTE.[10]

ETIOLOGY

1 A number of factors increase the risk of developing VTE (Table 26–1). These additive risk factors can be easily identified in clinical practice. Stasis of blood favors thrombogenesis in part through reduced clearance of activated clotting factors from sites of thrombus formation. The rate of blood flow in the venous circulation, particularly in the deep veins of the lower extremities, is relatively slow. Valves in the deep veins of the legs, as well as contraction of the calf and thigh muscles, facilitate the flow of blood back to the heart and lungs; thus, damage to the venous valves and periods of prolonged immobility result in venous stasis. Vessel obstruction, either from external compression or a thrombus, also promotes clot propagation. Reduced venous blood flow explains, at least in part, why numerous medical conditions and surgical procedures are associated with an increased risk of VTE (Table 26–1). Increased blood viscosity, seen in myeloproliferative disorders like polycythemia vera, for example, may also contribute to slowed blood flow and thrombus formation.

A growing list of hereditary deficiencies, gene mutations, and acquired diseases has been linked to hypercoagulability (see Table 26–1).[11] Activated protein C resistance is the most common genetic disorder of hypercoagulability, with a prevalence rate of about 5% in healthy people of Northern European ancestry, and a rate as high as 20% among patients with a first VTE.[11] About 90% of activated protein C resistance results from a mutation on factor V that renders it resistant to degradation by activated protein C.[12] This mutation is known as factor V Leiden, named after the city of Leiden, Holland, where the defect was first described in 1994. The prothrombin G20210A mutation is another common defect, occurring in about 4% of the general population and in about 6% of those with an initial VTE.[11] This mutation increases VTE risk by increasing the basal level of functionally normal prothrombin.[11] Although the rarity (present in <1% of the population) of inherited deficiencies of the natural anticoagulants protein C, protein S, and antithrombin, precludes accurate quantification of their effect on the risk of initial VTE, many experts believe the lifetime risk is high.[13] Conversely, excessively high concentrations of factors VIII, IX, and XI or fibrinogen also increase the risk of VTE.[11] Given the prevalence of these inherited abnormalities in the general population, some patients have multiple genetic defects that have additive effects in terms of increasing the lifetime thrombotic risk.[11]

Acquired disorders of hypercoagulability may result from malignancy, the presence of antiphospholipid antibodies, and

TABLE 26-1 Risk Factors for Venous Thromboembolism

Risk Factor	Comments/Examples
Age	Annual incidence increases from 1 per 100,000 in childhood to 1 per 100 in old age
History of VTE	Strongest known risk factor for recurrence, risk is highest during the first 6 months after VTE
Venous stasis	Acute medical illness requiring hospitalization
	Surgery (especially general anesthesia >30 minutes)
	Paralysis (e.g., status post-stroke, spinal cord injury) Immobility (e.g., plaster casts, status post-stroke, or spinal cord injury)
	Polycythemia vera
	Obesity
	Varicose veins
Vascular injury	Major orthopedic surgery (e.g., knee and hip replacement)
	Trauma (especially fractures of the pelvis, hip, or leg)
	Indwelling venous catheters
	Hypercoagulable states
	Malignancy, diagnosed or occult
	Activated protein C resistance/factor V Leiden
	Prothrombin (G20210A) gene mutation
	Protein C deficiency
	Protein S deficiency
	Antithrombin deficiency
	Factor VIII excess (>90th percentile)
	Factor XI excess (>90th percentile)
	Antiphospholipid antibodies
	Lupus anticoagulant
	Anticardiolipin antibodies
	Anti-β_2-glycoprotein I antibodies
	Dysfibrinogenemia
	Hyperhomocysteinemia
	Plasminogen activator inhibitor-1 excess
	Inflammatory bowel disease
	Nephrotic syndrome
	Paroxysmal nocturnal hemoglobinuria
	Pregnancy/postpartum
Drug therapy	Estrogen-containing contraception
	Estrogen replacement therapy
	Selective estrogen receptor modulators (e.g., tamoxifen, raloxifene)
	Cancer therapy
	Heparin-induced thrombocytopenia

VTE, venous thromboembolism.
Data from Rosendaal et al.,[17] Geerts et al.,[2] Giannakopoulos et al.[15]

estrogen use.[11] The strong link between cancer and thrombosis has been recognized since the late 1800s.[14] Tumor cells secrete a number of procoagulant substances that activate the coagulation cascade. Furthermore, patients with cancer often have suppressed levels of protein C, protein S, and antithrombin. It has been postulated that cancer cells use thrombotic mechanisms to recruit a blood supply (angiogenesis), metastasize, and create a barrier against host defense mechanisms.[14] Antiphospholipid antibodies, most commonly found in patients with autoimmune disorders such as systemic lupus erythematosus and inflammatory bowel disease, can cause venous and arterial thrombosis.[15] These antibodies are also associated with repeated pregnancy loss presumably caused by placental thrombosis.[16] The precise mechanism by which the antiphospholipid antibodies provoke thrombosis is unclear, but they appear to activate complement, the coagulation cascade and platelets, as well as to inhibit the anticoagulant activity of proteins C and S and fibrinolysis.[15] Estrogen-containing contraception, estrogen replacement therapy, and the selective estrogen receptor modulators are all linked to venous thrombosis.[17] Women with an underlying disorder of hypercoagulability are at particularly high risk of developing venous thrombosis while taking estrogens. Although the mechanisms are not clearly understood, estrogens increase serum clotting factor concentrations and induce activated protein C resistance. Increased serum estrogen concentrations may explain, in part, the increased risk of VTE observed during pregnancy and the immediate postpartum period.[16]

In many cases, VTE is the result of converging combinations of inherited and acquired thrombotic risk factors. Thus, many individuals with congenital hypercoagulable conditions experience a first VTE only after being placed in situations of high risk for thrombosis such as orthopedic surgery, immobilization, the use of estrogen-containing oral contraceptives, or pregnancy.[12]

PATHOPHYSIOLOGY

The arrest of bleeding following vascular injury (hemostasis) is an amazingly complex process that is essential to life. Within the vascular system, blood remains in a fluid state, transporting oxygen, nutrients, plasma proteins, and waste. With vascular injury, a dynamic series of reactions involving a complex interplay of thrombogenic and antithrombotic stimuli result in the local formation of a hemostatic plug that seals the vessel wall and prevents further blood loss but does not spread to other areas of the vasculature (Figs. 26–2, 26–3, 26–4).[18] A disruption of this delicate system of checks and balances may lead to inappropriate clot formation within the blood vessel that subsequently obstructs blood flow or embolizes to a distant vascular bed. In the late 1800s, Dr. Rudolf Virchow, a German pathologist, recognized the role played by blood vessels, circulating elements in the blood, and the speed of blood flow in the regulation of clot formation (Table 26–2).[10] Alterations in any one of these elements, known today as the Virchow triad, may lead to pathologic clot formation.

Hemostasis occurs in three distinct but overlapping steps: initiation, amplification, and propagation (see Fig. 26–4).[18] Under normal circumstances, the endothelial cells that form the intima of vessels maintain blood flow by physically separating extravascular collagen and tissue factor from platelets and by producing substances that inhibit platelet adherence and prevent the activation of the coagulation cascade. Vascular injury allows key components of the coagulation process, namely platelets and factor VIII complexed to von Willebrand factor to come into contact with collagen and tissue factor bearing cells in the extravascular space initiating the hemostatic process (see Fig. 26–3). During initiation, tissue factor bearing cells produce small (picomolar) amounts of thrombin via what has traditionally been termed the "extrinsic" coagulation pathway (namely the factor VIIa/tissue factor complex and the factor Xa/Va complex).[19] A major function of this thrombin is amplification of the hemostatic process by inducing platelets partially activated during adherence to collagen at the site of vascular injury to higher levels of procoagulant activity. This dual activation by collagen and thrombin is a mechanism by which the most procoagulant form of activated platelets are produced at the site of vascular injury.[18] In addition, the thrombin formed during initiation activates cofactors V and VIII and factor XI on platelet surfaces in preparation for large-scale thrombin production. This so-called propagation phase involves much of what has traditionally been termed the "intrinsic" coagulation pathway (namely factor XIa, the factor IXa/VIIIa complex and the factor Xa/Va complex) occurring on the negatively charged phospholipid surfaces of activated platelets (see Fig. 26–4). Thus while the coagulation cascade has historically been divided into distinct parts: the intrinsic, extrinsic, and common pathways, this artificial division is somewhat misleading, as the intrinsic and extrinsic pathways cannot function as independent, redundant pathways in vivo, but are both required for physiologic hemostasis operating on different cell surfaces and playing unique roles.[18]

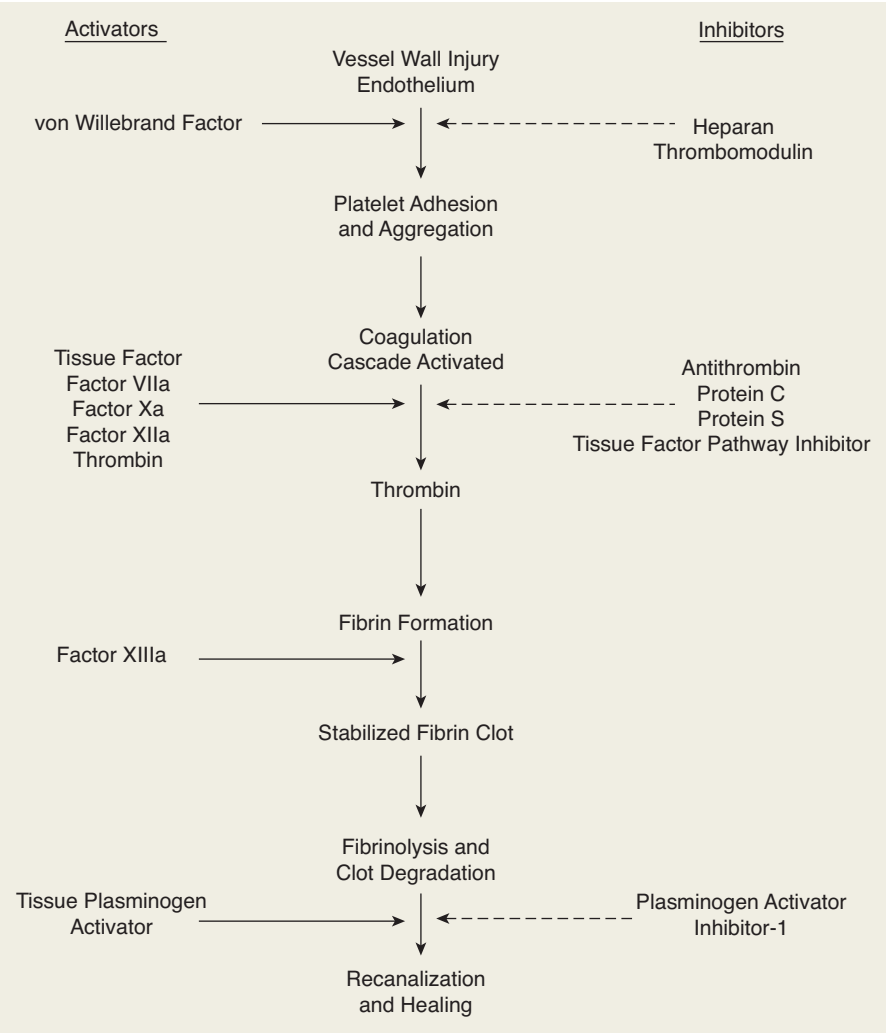

FIGURE 26-2. Hemostasis and thrombosis.

The final step in hemostasis is the thrombin-mediated conversion of fibrinogen to form fibrin monomers. As fibrin monomers reach a critical concentration, they begin to precipitate and polymerize to form fibrin strands. Factor XIIIa covalently bonds these strands to one another. Local deposition of fibrin forms an extensive meshwork that surrounds and encases aggregated platelets to form a stabilized clot that seals the site of vascular injury and prevents blood loss.[20] Coagulation reactions are eventually terminated when this expanding meshwork of platelets and fibrin "paves over" the initiation site and activated factors are unable to diffuse through the overlying layer of clot.[18]

Normally, a number of tempering mechanisms control coagulation (see Table 26–2 and Fig. 26–2).[18] Without effective self-regulation, the coagulation cascade would proceed unabated causing vascular occlusion at the site of injury. The intact endothelium adjacent to the damaged tissue actively secretes several antithrombotic substances. As its name implies, thrombomodulin modulates thrombin activity by converting protein C to its active form (activated protein C [aPC]). When joined with its cofactor protein S, aPC enzymatically inactivates factors Va and VIIIa. The physiologic role of aPC is to prevent coagulation reactions from spreading to healthy, uninjured vessel walls. Antithrombin is a circulating protein that inhibits thrombin and factor Xa. Heparan sulfate, a heparin-like compound secreted by endothelial cells, exponentially accelerates antithrombin activity. By a similar mechanism, heparin cofactor II also inhibits thrombin. Tissue factor pathway inhibitor plays an important role by regulating the initiation of the coagulation cascade. When these self-regulatory mechanisms are intact, the formation of the fibrin clot is limited to the zone of tissue injury. However, disruptions in the system, so-called hypercoagulable states, often result in pathologic thrombosis.

The fibrinolytic system is responsible for the dissolution of formed blood clots.[21] An inactive proenzyme, plasminogen, is converted to an active enzyme, plasmin, that degrades the fibrin mesh into soluble end products collectively known as fibrin split products or fibrin degradation products.[21] The fibrinolytic system is also under the control of a series of stimulatory and inhibitory substances. Tissue plasminogen activator and urokinase plasminogen activator convert plasminogen to plasmin. Plasminogen activator inhibitor-1 inhibits the plasminogen activators, and α_2-antiplasmin inhibits plasmin activity. Impaired activation of the fibrinolytic system has also been linked to hypercoagulability and thrombotic complications.[21]

CLINICAL PRESENTATION AND DIAGNOSIS

Although a thrombus can form in any part of the venous circulation, the majority begin in the lower extremities. Once formed, a venous thrombus may either (a) remain asymptomatic, (b) spontaneously lyse, (c) obstruct the venous circulation, (d) propagate into more proximal veins, (e) embolize, or (f) act in any combination of these ways.[22] Many patients with VTE never develop symptoms

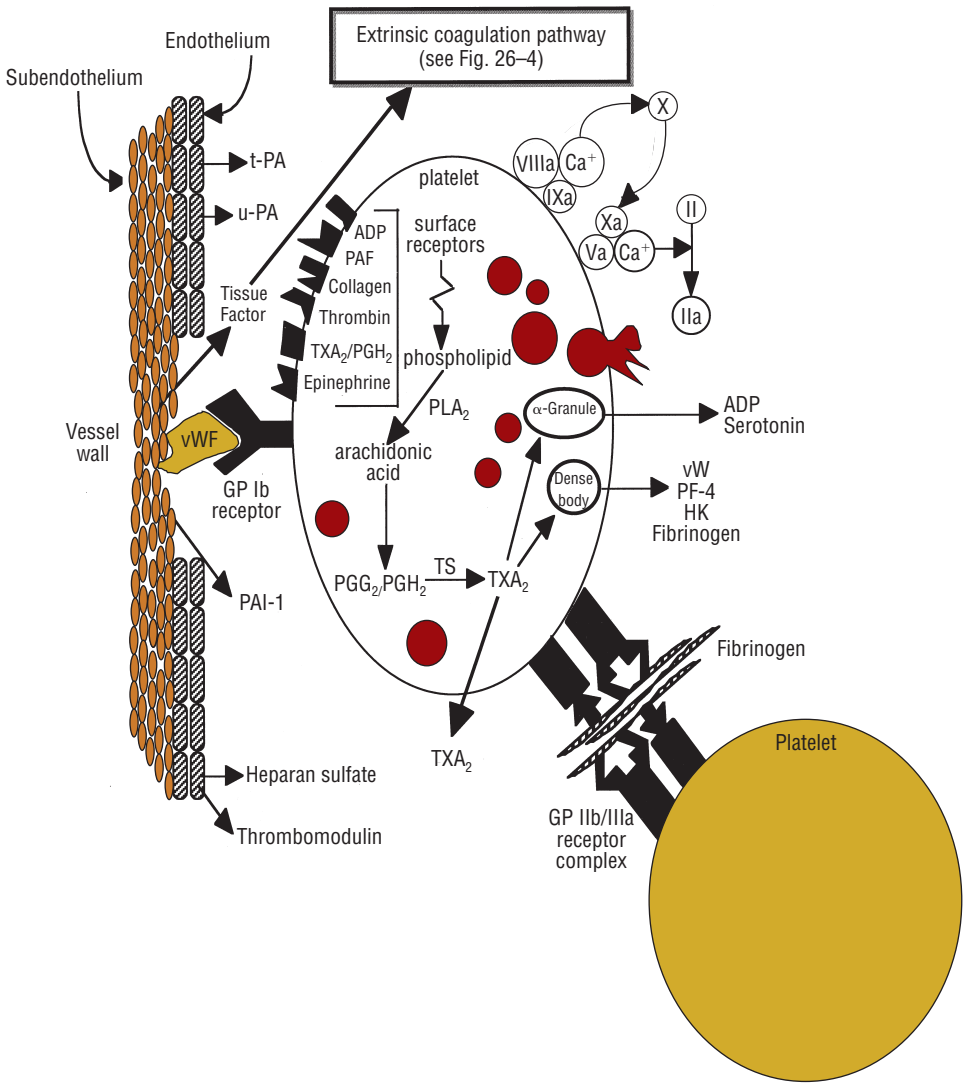

FIGURE 26-3. Vascular injury and thrombosis. (ADP, adenosine diphosphate; CO, cyclooxygenase; GP Ib, glycoprotein Ib; GP IIb/IIa, glycoprotein IIb/IIa; HK, high-molecular-weight kininogen; PAF, platelet-activating factor; PAI-1, plasminogen activator inhibitor; PF4, platelet factor 4; PGG/PGH, prostaglandins; PGI, prostacyclin; PLA, phospholipase A; TS, thromboxane synthetase; TXA_2, thromboxane A_2; t-PA, tissue plasmogen activator; u-PA, urokinase plasmogen activator; vWF, von Willebrand factor.)

from the acute event. However, even in the absence of symptoms, patients may develop long-term consequences, such as the postthrombotic syndrome, CTPH, and recurrent VTE. The symptoms of DVT or PE (Tables 26–3, 26–4), are nonspecific and objective tests are required to confirm or exclude the diagnosis.[23] Patients with DVT frequently present with unilateral leg pain and swelling. The postthrombotic syndrome, a long-term complication of DVT caused by damage to the venous valves, also produces similar symptoms including chronic lower extremity swelling, pain, tenderness, skin discoloration, and ulceration. Symptomatic PE often produces dyspnea, tachypnea, and tachycardia.[24] Hemoptysis, while distressing, occurs in less than one third of patients. Cardiovascular collapse, characterized by cyanosis, shock, and oliguria, is an ominous sign.

2 Given that VTE can be debilitating or fatal, it is important to treat it quickly and aggressively.[6] Conversely, because major bleeding induced by antithrombotic drugs can be equally harmful, it is important to avoid treatment when the diagnosis is not a reasonable certainty.[25] Assessment of the patient's status should focus on the search for risk factors in the patient's medical history (see Table 26–1). Venous thrombosis is uncommon in the absence of risk factors, and the effects of these risks are additive. Even in the presence of mild, seemingly inconsequential symptoms, VTE should be strongly suspected in those with multiple risk factors.

Because radiographic contrast studies are the most accurate and reliable methods for the diagnosis of VTE, they are considered the gold standards in clinical trials.[26] Contrast venography allows visualization of the entire venous system in the lower extremity and abdomen. Pulmonary angiography allows the visualization of the pulmonary arteries. The diagnosis of VTE can be made if there is a persistent intraluminal filling defect observed on multiple radiographic films. Contrast studies are expensive, invasive procedures that are technically difficult to perform and evaluate. Severely ill patients often are unable to tolerate the procedure, and many develop hypotension and cardiac arrhythmias. Furthermore, the contrast medium is irritating to vessel walls and toxic to the kidneys. For these reasons, noninvasive tests, such as ultrasonography, computed tomography scans, and the ventilation–perfusion scan, are frequently used in clinical practice for the initial evaluation of patients with suspected VTE.

D-dimer is a simple blood test frequently used in the diagnostic evaluation of patients suspected to have VTE.[25] D-dimer is a

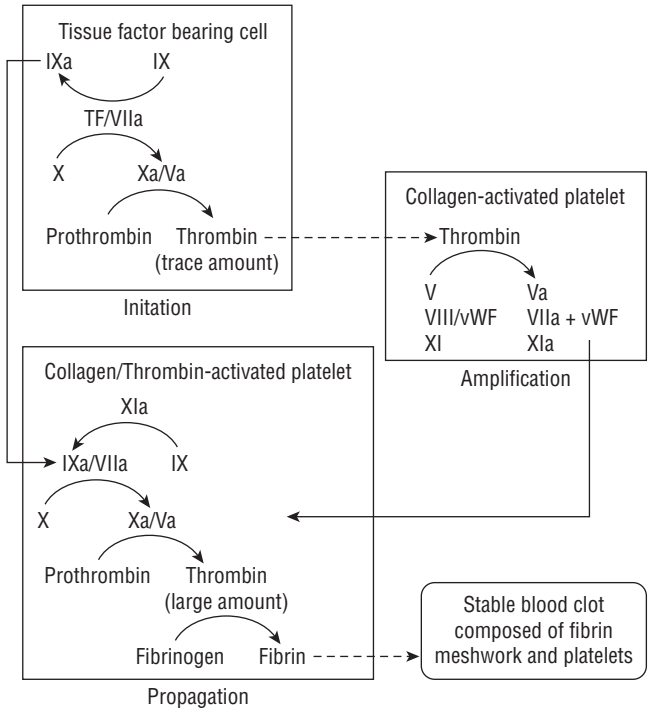

FIGURE 26-4. Coagulation cascade. (TF, tissue factor; vWF, von Willebrand factor.)

degradation product of a fibrin blood clot and levels of D-dimer are significantly elevated in patients with acute thrombosis. Although the D-dimer test is a very sensitive marker of clot formation, it is not sufficiently specific. A variety of conditions can cause elevations of serum D-dimer, including recent surgery or trauma, pregnancy, and cancer. While a negative test can help to "rule out" a DVT or PE, a positive test is not conclusive evidence of the diagnosis.

Clinical assessment significantly improves the diagnostic accuracy of noninvasive tests such as ultrasonography, ventilation–perfusion scanning, and D-dimer.[27] Simple assessment checklists can be used to determine if a patient has a high, moderate, or low probability of a DVT or PE (Table 26–5). Patients with a high pretest probability of VTE have a greater than 60% chance of having VTE, compared with only 5% for the low pretest probability group. Clinical assessment can rule in or out the diagnosis of VTE with reasonable certainty when the results are consistent with those of a noninvasive test.[25] For example, in patients with a high or moderate pretest probability of VTE and an abnormal lower-extremity ultrasonogram, the diagnosis of VTE can be reasonably concluded. In patients with a low pretest probability of VTE and a negative D-dimer test (≤500 ng/mL), the diagnosis of VTE can be reasonably excluded without radiographic testing. However, if the results of the clinical assessment and the ultrasonogram are discordant, additional tests should be performed to confirm the diagnosis.

TABLE 26-2 Factors Regulating Hemostasis and Thrombosis

	Thrombogenic	Antithrombotic
Vessel wall	Exposed subendothelium	Preserved endothelial integrity
	Tissue factor	Heparan sulfate
	Plasminogen activator inhibitor-1	Dermatan sulfate
		Thrombomodulin
		Tissue plasminogen activator
		Urokinase plasminogen activator
Circulating elements	Platelets	Antithrombin
	Platelet activating factor	Heparin cofactor II
	The clotting factors	Protein C
	Prothrombin (factor II)	Protein S
	Fibrinogen (factor I)	Plasminogen
	von Willebrand factor	Tissue factor pathway inhibitor
	β_2-Antiplasmin	Proteolytic enzymes
Blood flow	Slow rate of flow	Fast rate of flow
	Turbulent flow	Laminar flow

TABLE 26-3 Clinical Presentation of Deep Vein Thrombosis

General

Venous thromboembolism most commonly develops in patients with identifiable risk factors (see Table 26-1) during or following a period of acute illness or hospitalization. Many, perhaps the majority, of patients have asymptomatic disease. Patients may die suddenly of pulmonary embolism.

Symptoms

The patient may complain of leg swelling, pain, or warmth. Symptoms are nonspecific and objective testing must be performed to establish the diagnosis.

Signs

The patient's superficial veins may be dilated and a "palpable cord" may be felt in the affected leg.

The patient may experience pain in back of the knee when the examiner dorsiflexes the foot of the affected leg (known as Homans sign).

Laboratory tests

Serum concentrations of D-dimer, a byproduct of thrombin generation, is nearly always elevated.

The patient may have an elevated erythrocyte sedimentation rate and white blood cell count.

Diagnostic tests

Duplex ultrasonography is the most commonly used test to diagnosis deep vein thrombosis. It is a noninvasive test that can measure the rate and direction of blood flow and visualize clot formation in proximal veins of the legs. It cannot reliably detect small blood clots in distal veins. Coupled with a careful clinical assessment, it can rule in or out the diagnosis in the majority of cases.

Venography (also known as phlebography) is the gold standard for the diagnosis of deep vein thrombosis. However, it is an invasive test that involves injection of radiopaque contrast dye into a foot vein. It is expensive and can cause anaphylaxis and nephrotoxicity.

PHARMACOLOGIC AGENTS USED IN THE MANAGEMENT OF VENOUS THROMBOEMBOLISM

The following agents are most commonly used in the prevention and treatment of VTE. A brief overview of selected investigational agents is also provided.

UNFRACTIONATED HEPARIN

Unfractionated heparin (UFH) has been used for the prevention and treatment of thrombosis for decades.[5] Commercially available UFH preparations are derived from bovine lung or porcine intestinal mucosa. Although some differences exist between the two sources, no differences in antithrombotic activity have been demonstrated. Today, UFH and the low-molecular-weight heparins (LMWHs) are the most commonly used therapies for the acute treatment of venous thrombosis.[6]

Pharmacology

Unfractionated heparin is a heterogeneous mixture of sulfated mucopolysaccharides of variable lengths and pharmacologic properties (Table 26–6).[5] Each heparin molecule is composed of

TABLE 26-4 Clinical Presentation of Pulmonary Embolism

General

Pulmonary embolism (PE) most commonly develops in patients with risk factors for venous thromboembolism (see Table 26–1) during or following a hospitalization. Although many patients develop a symptomatic deep vein thrombosis prior to developing a PE, many do not. Patients may die suddenly before effective treatment can be initiated.

Symptoms

The patient may complain of cough, chest pain, chest tightness, shortness of breath, or palpitation. The patient may spit or cough up blood (hemoptysis). When PE is massive, the patient may complain of dizziness or lightheadedness. Symptoms may be confused for a myocardial infarction, requiring objective testing to establish the diagnosis.

Signs

The patient may have tachypnea (increased respiratory rate) and tachycardia (increased heart rate). The patient may appear diaphoretic (sweaty). The patient's neck veins may be distended. In massive PE, the patient may appear cyanotic and become hypotensive. In such cases, oxygen saturation by pulse oximetry or arterial blood gas will likely indicate that the patient is hypoxic. In the worse cases, the patient may go into circulatory shock and die within minutes.

Laboratory tests

Serum concentrations of D-dimer, a byproduct of thrombin generation, are nearly always elevated.

The patient may have an elevated erythrocyte sedimentation rate and white blood cell count.

Diagnostic tests

Computerized tomography (CT) scan is the most commonly used test to diagnose PE but some centers still use the ventilation-perfusion (V/Q) scan. Spiral CT scans can detect emboli in the pulmonary arteries. A V/Q scan measures the distribution of blood and air flow in the lungs. When there is a large mismatch between blood and air flow in one area of the lung, there is a high probability that the patient has a PE.

Pulmonary angiography is the gold standard for the diagnosis of PE. However, it is an invasive test that involves injection of radiopaque contrast dye into the pulmonary artery. The test is expensive and associated with a significant risk of mortality.

TABLE 26-5 Clinical Assessment Models for Deep Vein Thrombosis and Pulmonary Embolism

Pretest Probability of Deep Vein Thrombosis

Clinical feature	Score
Tenderness along entire deep vein system	1.0
Swelling of the entire leg	1.0
Greater than 3 cm difference in calf circumference	1.0
Pitting edema	1.0
Collateral superficial veins	1.0
Risk factors present:	
Active cancer	1.0
Prolonged immobility or paralysis	1.0
Recent surgery or major medical illness	1.0
Alternative diagnosis likely (ruptured Baker cyst, rheumatoid arthritis, superficial thrombophlebitis, or infective cellulitis)	−2.0

Score ≥3 = high probability; 1–2 = moderate probability; ≤0 = low probability

Pretest Probability of Pulmonary Embolism

Clinical feature	Score
Deep vein thrombosis suspected	
Clinical features of deep vein thrombosis	3.0
Recent prolonged immobility or surgery	1.5
Active cancer	1.0
History of deep vein thrombosis or pulmonary embolism	1.5
Hemoptysis	1.0
Resting heart rate >100 beats/min	1.5
No alternative explanation for acute shortness of breath or chest pain	3.0

Score ≥6 = high probability; 2–6 = moderate probability; ≤1.5 = low probability

Adapted from Hunt.[27]

repetitive units of D-glycosamine and uronic acid. The molecular weight of UFH molecules ranges from 3,000 to 30,000 daltons, with a mean of 15,000 daltons. The anticoagulant profile and clearance of each UFH molecule varies based on its length. The smaller chains are cleared less rapidly than their longer counterparts.[5]

The anticoagulant effect of UFH is mediated through a specific pentasaccharide sequence on the heparin molecule that binds to antithrombin, provoking a conformational change (Fig. 26–5). Only one third of the UFH molecules possess the unique pentasaccharide sequence with affinity for antithrombin. The UFH–antithrombin complex is 100 to 1,000 times more potent as an anticoagulant compared to antithrombin alone. Antithrombin inhibits the activity of several clotting factors including IXa, Xa, XIIa, and thrombin. Through its action on thrombin, the UFH–antithrombin complex also inhibits the thrombin-induced activation of factors V and VIII.[5] UFH prevents the growth and propagation of a formed thrombus and allows the patient's own thrombolytic system to degrade the clot.

Factors IIa (thrombin) and Xa are the most sensitive to inhibition by the UFH–antithrombin complex. To inactivate thrombin, the heparin molecule must form a ternary complex bridging between antithrombin and thrombin (see Fig. 26–5). Only molecules that contain more than 18 saccharides are able to bind to both antithrombin and thrombin simultaneously. Smaller heparin molecules cannot facilitate the interaction between antithrombin and thrombin. In contrast, the inactivation of factor Xa does not require UFH to form a bridge with antithrombin. It only requires that UFH bind to antithrombin using the specific pentasaccharide sequence. Heparin molecules with as few as 5 saccharide units are able to catalyze the inhibition of factor Xa. Heparin uncouples from antithrombin after it has produced its effect and quickly recouples with another antithrombin molecule. Because of its relatively large size, the UFH–antithrombin complex is incapable of inactivating thrombin or factor Xa within a formed clot or bound to surfaces. At high doses, UFH also binds to heparin cofactor II, further inhibiting the activity of thrombin. UFH increases the release of tissue factor pathway inhibitor from vascular endothelium, augmenting its inhibitory effect on factor Xa. UFH, especially high-molecular-weight heparin fractions, also binds to platelets and inhibits platelet aggregation.[5]

Pharmacokinetics

Unfractionated heparin is not reliably absorbed when taken orally as a result of its large molecular size and anionic structure. The bioavailability and biologic activity of UFH is limited by its propensity to bind to plasma proteins, platelet factor 4 (PF4), macrophages, fibrinogen, lipoproteins, and endothelial cells.[5] This may explain the substantial inter- and intra-patient variability observed in the anticoagulation response to UFH.[5]

The subcutaneous bioavailability of UFH is dose dependent and ranges from 30% at low doses to as much as 70% at high doses. Higher doses presumably saturate protein-binding sites, thereby permitting a larger proportion to reach the systemic circulation. The onset of anticoagulant effect is usually evident 1 to 2 hours after subcutaneous injection and peaks at 3 hours.[28] When UFH is administered via the IV route, a continuous infusion is preferable. Intermittent IV boluses produce relatively high peaks in anticoagulation activity and have been associated with a greater risk of major bleeding.[6] Intramuscular administration is discouraged because of erratic absorption and risk of large hematoma formation.

Unfractionated heparin has a dose-dependent half-life of approximately 30 to 90 minutes, but may be prolonged to as much as 150 minutes when given in high doses to some patients.[5] There are two primary mechanisms for the elimination of UFH. The relative contribution of each mechanism to the total clearance of heparin is related

TABLE 26-6 Comparison of the Chemical and Pharmacokinetic Properties of Antithrombotic Drugs Used for Venous Thrombosis

Agent	FDA Approved	Method of Preparation	Mean Molecular Weight (Daltons)	Plasma Half-Life	Anti-Xa: Anti-IIa Activity	Bioavailability
Unfractionated heparin	Yes	Extracted from porcine gut mucosa or beef lung	≈15,000	30–90 min (dose dependent)	1:1	SC: 30–70% (dose dependent)
Low-molecular-weight heparins						
Dalteparin (Fragmin)	Yes	Nitrous acid depolymerization	≈6,000	119–139 min	2.7:1	SC: 87%
Enoxaparin (Lovenox)	Yes	Benzoylation and alkaline depolymerization	≈4,200	129–180 min	3.8:1	SC: 92%
Tinzaparin (Innohep)	Yes	Heparinase digestion	≈4,500	111–234 min	2.8:1	SC: 90%
Heparinoid						
Danaparoid (Orgaran)	Yes (no longer marketed in U.S.)	Extracted from porcine gut mucosa	≈6,500	22–24 h	20:1	SC: 95%
Anti-factor Xa inhibitors						
Fondaparinux (Arixtra)	Yes	Synthetic	1,728	15–18 h	100% anti-Xa	SC: 100%
Idraparinux and biotinylated idraparinux	No	Synthetic	≈1,700	≈80 h	100% anti-Xa	SC: 100%
Rivaroxaban (Xarelto)	No (Available in EU and Canada)	Synthetic	NA	7-11 h	100% anti-Xa	PO: 80%-100%
Abipxaban	No	Synthetic	460	9-14 h	100% anti-Xa	PO: 50%
Direct thrombin inhibitors						
Argatroban (Argatroban)	Yes	Synthetic	509	30–50 min	100% anti-IIa	
Bivalirudin (Angiomax)	Yes	Semisynthetic	2,180	25 min	100% anti-IIa	
Desirudin (Iprivask)	Yes	Recombinant DNA technology	6,964	120 min	100% anti-IIa	SC: >90%
Lepirudin (Refludan)	Yes	Recombinant DNA technology	6,980	80 min	100% anti-IIa	SC: 70%
Dabigatran	Yes (for stroke prevention in atrial fibrillation)	Synthetic	471	14 h	100% anti-IIa	Oral: 7%
Vitamin K antagonists						
Warfarin (Coumadin)	Yes	Synthetic	330	40 h	1:1	Oral: 90–100%

SC, subcutaneous; NA, not available.
Data from Nutescu et al.,[53] Abrams et al.,[97] and Karthikeyan et al.[40]

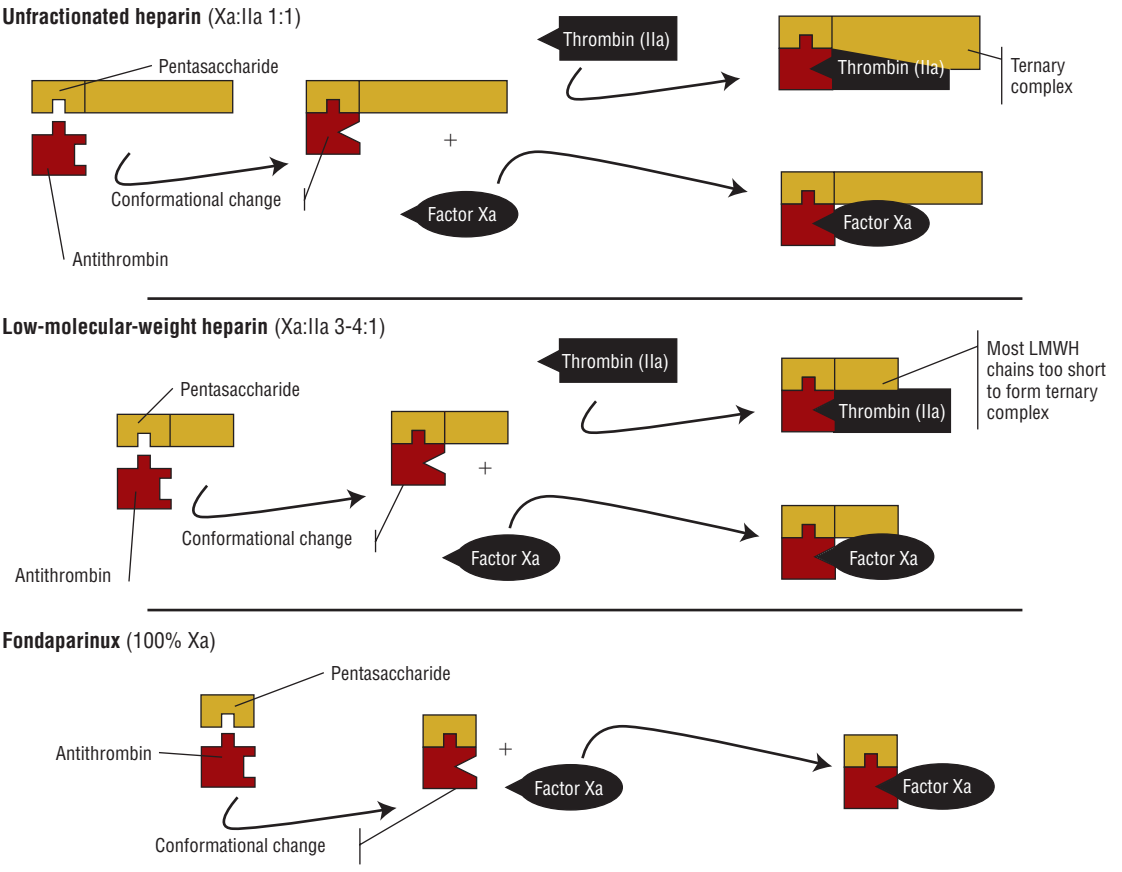

FIGURE 26-5. Pharmacologic activity of unfractionated heparin, low-molecular-weight heparins (LMWHs), and fondaparinux.

to the dose and size of the UFH molecules. One mechanism is a rapid, but saturable zero-order process. Heparinases and desulfatases enzymatically inactivate heparin molecules bound to endothelial cells and macrophages, reducing them to smaller and less sulfated molecules.[5] Heparin is also eliminated renally. This first-order process is slower and nonsaturable. Low doses of UFH are cleared principally by the saturable, rapid, zero-order mechanism, whereas the renal route predominates at very high doses. With typical therapeutic regimens, a combination of the two mechanisms are used to eliminate UFH with the saturable mechanism predominating. Renal and hepatic dysfunction reduces the rate of clearance of UFH. Patients with active thrombosis may eliminate UFH more rapidly, possibly because of increased binding to acute phase reactants.[28]

Dose and Administration

The dose and route of administration for UFH are based on the indication, the therapeutic goals, and the patient's individual response to therapy. The dose of UFH is expressed in units of activity. The number of units per milligram is variable and depends on the manufacturing process. For the prevention of VTE, UFH is given by subcutaneous injection in the abdominal fat layer over the iliac crest. The typical dose for prophylaxis is 5,000 units every 8 to 12 hours. When immediate and full anticoagulation is required, a weight-based IV bolus dose followed by a continuous infusion is preferred (Table 26–7).[5] Subcutaneous UFH (initial dose of 333 units/kg followed by 250 units/kg every 12 hours) also provides adequate therapeutic anticoagulation for the treatment of acute VTE.[29]

Therapeutic Monitoring

3 Administration of UFH has traditionally required close monitoring because of the unpredictable anticoagulant patient response.[5] Several tests are available to monitor UFH therapy including whole blood clotting time, activated partial thromboplastin time (aPTT), activated clotting time (ACT), antifactor Xa activity, and plasma heparin concentrations. The aPTT is the most widely used test to determine the degree of therapeutic anticoagulation. The therapeutic range of aPTT has traditionally been considered to be 1.5 to 2.5 times the mean normal control value.[5] Many currently available aPTT reagents do not accurately measure the response to heparin within this fixed therapeutic range; thus, the use of a fixed aPTT therapeutic range of 1.5 to 2.5 times the control represents a subtherapeutic dose of UFH in many instances.[5] Because of substantial interlaboratory variability in the aPTT, an institution-specific aPTT therapeutic range that correlates with a plasma heparin concentration of 0.3 to 0.7 units/mL by an amidolytic antifactor Xa assay should be established.[5]

Although most experts advocate using the aPTT to monitor UFH provided that institution-specific therapeutic ranges are defined, the use of aPTT has several limitations. First, preanalytical variables such as reagent sensitivity, temperature, phlebotomy methods, and hemodilution may result in aPTT results that do not correlate with the in vivo level of heparin anticoagulation present.[28] Second, the aPTT response exhibits diurnal variation, with a peak response occurring around 3 AM during continuous IV infusion. Adjusting infusion rates in response to this diurnal variation could lead to subsequent over- or underdosing.[30] Third, the aPTT is prolonged beyond measurable limits when the heparin concentration exceeds 1 unit/mL; consequently, the aPTT is unsuitable for monitoring heparin therapy in patients who require doses of heparin that will produce serum concentrations >1 unit/mL. The ACT is the most suitable assay when high doses of heparin are used, especially during coronary angioplasty or coronary bypass surgery.[5] Fourth, the lower-weight heparin fragments accumulate but have little effect on the aPTT in vivo.[28] Lastly, the data supporting the currently recommended heparin concentration therapeutic range is not derived from scientifically rigorous research.[5]

The aPTT should be measured prior to the initiation of therapy to determine the patient's baseline. When administered by IV infusion, the response to therapy should be measured 6 hours after the initiation of therapy or a dose change. This is usually sufficient time for heparin to reach steady state. The dose of heparin should be promptly adjusted based on the patient's response and the institution-specific therapeutic range (see Table 26–7).[28]

Some patients with acute VTE and myocardial infarction have a diminished response to UFH (so-called heparin resistance), presumably because of variations in the plasma concentrations of heparin-binding proteins. Some patients are reported to have acute elevations in factor VIII, preventing the prolongation of the aPTT by UFH. In some cases, antithrombin deficiency might be the culprit. The possibility of this phenomenon should be suspected in patients who require more than 35,000 units of UFH per 24-hour period. The recommended management of patients with "heparin resistance" is to adjust the UFH dose based on antifactor Xa concentrations.[5]

TABLE 26-7 Weight-Based[a] Dosing for Unfractionated Heparin Administered by Continuous Intravenous Infusion

Indication	Initial Loading Dose	Initial Infusion Rate
Deep venous thrombosis/pulmonary embolism	80–100 units/kg Maximum = 10,000 units	17–20 units/kg/h Maximum = 2,300 units/h
Activated Partial Thromboplastin Time (seconds)	**Maintenance Infusion Rate**	
	Dose adjustment	
<37 (or >12 s below institution-specific therapeutic range)	80 units/kg bolus then increase infusion by 4 units/kg/h	
37–47 (or 1–12 s below institution-specific therapeutic range)	40 units/kg bolus then increase infusion by 2 units/kg/h	
48–71 (or within institution-specific therapeutic range)	No change	
72–93 (or 1–22 s above institution-specific therapeutic range)	Decrease infusion by 2 units/kg/h	
>93 (or <22 s above institution-specific therapeutic range)	Hold infusion for 1 h then decrease by 3 units/kg/h	

[a] Use actual body weight for all calculations. Adjusted body weight may be used for obese patients (>130% of ideal body weight).

Adverse Effects

4 Bleeding is the primary adverse effect associated with all anticoagulant drugs (Table 26–8).[3] There is not solid evidence linking supratherapeutic aPTT values and the risk for bleeding in patients receiving UFH. The risk for bleeding is more closely related to underlying risk factors than to high aPTT values.[30] Therefore, UFH should not be administered to patients with contraindications to anticoagulation therapy (Table 26–9). Low-dose subcutaneous UFH is associated with a minimal risk of major bleeding. The rates of major bleeding for patients receiving full therapeutic doses of UFH range from 0% to 2%.[3] The presence of concomitant bleeding risks such as thrombocytopenia, the use other antithrombotic therapy, and a preexisting source of bleeding increase the risk of UFH-induced hemorrhage. The risk of bleeding also increases with age. Recent surgery, hemostatic defects, heavy alcohol consumption, renal failure, peptic ulcers, and neoplasms also increase the risk of major bleeding while receiving UFH.[3]

TABLE 26-8 Risk Factors for Major Bleeding While Taking Anticoagulation Therapy

Anticoagulation intensity (e.g., international normalized ratio >4.0)
Initiation of therapy (first few days and weeks)
Unstable anticoagulation response
Age >65 years
Concurrent antiplatelet drug use
Concurrent nonsteroidal antiinflammatory drug use
History of gastrointestinal bleeding
Recent surgery or trauma
High risk for fall/trauma
Heavy alcohol use
Renal failure
Cerebrovascular disease
Malignancy

From Schulman et al.[3]

Anatomic sites commonly associated with UFH-related bleeding include the gastrointestinal and urinary tracts, as well as soft tissues. Minor bleeding, such as epistaxis, gingival bleeding, and prolonged bleeding from cuts, is frequently reported. Bruising from minor trauma and at the sites of subcutaneous injections and venous access is also common. Local irritation, mild pain, erythema, histamine-like reactions, and hematoma can occur during UFH administration. Even small amounts of bleeding into critical sites such as the central nervous system (CNS) or the structures of the eye can cause catastrophic consequences.

Heparin-induced thrombocytopenia (HIT) is a serious drug-induced problem requiring immediate intervention (see Heparin-Induced Thrombocytopenia below).[31] A baseline platelet count should be obtained before UFH therapy is initiated. If the patient has received UFH within the previous 100 days, or if previous UFH exposure is uncertain, a repeat platelet count should be performed within 24 hours.[31] Monitoring platelet counts every other day for 14 days or until UFH therapy is stopped, whichever occurs first, is recommended for patients who are receiving therapeutic doses of UFH.[31]

Long-term UFH has been reported to cause alopecia, priapism, and suppressed aldosterone synthesis with subsequent hyperkalemia. The use of UFH in doses ≥20,000 units/day for more than 6 months, especially during pregnancy, is associated with significant bone loss and may lead to osteoporosis.[30] Few drug interactions are reported with UFH. Concurrent use with other antithrombotic drugs, thrombolytics, and antiplatelet agents increases the risk of bleeding, however.

TABLE 26-9 Contraindications to Anticoagulation Therapy

General
Active major bleeding
Hemophilia or other hemorrhagic tendencies
Severe liver disease with elevated baseline PT
Severe thrombocytopenia (platelet count <20,000 mm^3)
Malignant hypertension
Inability to meticulously supervise and monitor treatment
Product-specific contraindications
Argatroban
Hypersensitivity to argatroban
Bivalirudin
Hypersensitivity to bivalirubin
Fondaparinux
Hypersensitivity to fondaparinux
Severe renal insufficiency (creatinine clearance <30 mL/min)
Body weight <50 kg (prophylaxis only)
Bacterial endocarditis
Thrombocytopenia with a positive in vitro test for anti-platelet antibodies in the presence of fondaparinux
Lepirudin
Hypersensitivity to hirudins
LMWHs
Hypersensitivity to LMWH, UFH, pork products, methylparaben, or propylparaben
Thrombocytopenia associated with a positive in vitro test for anti-platelet antibody in the presence of LMWH
UFH
Hypersensitivity to UFH
Thrombocytopenia associated with a positive in vitro test for anti-platelet antibody in the presence of UFH
Warfarin
Hypersensitivity to warfarin
Pregnancy
History of warfarin-induced skin necrosis
Inability to obtain regular PT/INR measurements
Inappropriate medication use or lifestyle behaviors

HIT, heparin-induced thrombocytopenia; INR, international normalized ratio; LMWH, low-molecularweight heparin; PT, prothrombin time; UFH, unfractionated heparin.

Management of Bleeding and Excessive Anticoagulation

Hemorrhage can occur at any site in patients receiving UFH and close monitoring for signs and symptoms of bleeding is crucial.[3,5] In addition to an appropriate coagulation study to measure the response to UFH, it is necessary to regularly monitor hemoglobin, hematocrit, and blood pressure. Bleeding can produce a wide variety of symptoms, depending on the site of hemorrhage. Symptoms can include severe headache, joint pain, chest pain, abdominal pain, swelling, tarry stools, frank hematuria, or the passage of bright red blood through the rectum. Life-threatening bleeding, either as a consequence of a significant volume loss or because of the location (e.g., bleeding into a critical space), must be recognized swiftly and immediately treated. Critical areas include intracranial, pericardial, and intraocular sites, as well as the adrenal glands.

When major bleeding occurs, UFH should be immediately discontinued and the underlying source of bleeding should be identified and treated. Intravenous protamine sulfate, given in a dose of 1 mg per 100 units of UFH up to a maximum of 50 mg, can be administered to reverse the anticoagulant effects of UFH.[5] Protamine sulfate has intrinsic anticoagulation activity, but when administered with UFH, it forms a stable salt that results in the loss of anticoagulation activity of both drugs. Protamine sulfate neutralizes UFH in 5 minutes, and its activity persists for 2 hours. It should be given by slow IV infusion.[5] In cases of large heparin overdoses or in patients with renal failure, a "rebound" effect may occur with a return of some anticoagulant activity several hours after the administration of protamine sulfate. Therefore, the patient's aPTT should be closely monitored. Multiple doses or prolonged infusion of protamine sulfate may be necessary if hemorrhage continues.[5]

Use in Special Populations

Heparin-related compounds such as UFH or LMWH are the anticoagulants of choice during pregnancy.[16] Because UFH does not cross the placenta, it is not associated with teratogenicity or fetal bleeding complications.[16] UFH should be used cautiously during the last trimester of pregnancy and the peripartum period because of the risk of maternal hemorrhage. Induction of labor is advisable so that UFH can be discontinued prior to delivery to minimize the risk for excessive bleeding during delivery. Long-term use of UFH during pregnancy may result in bone loss and increased risk for

TABLE 26-10 FDA-Approved Indications and Doses for Low-Molecular-Weight Heparins

Indications	Enoxaparin	Dalteparin	Tinzaparin
Hip-replacement surgery (prophylaxis)	30 mg SC q 12 h initiated 12–24 h after surgery *or* 40 mg SC q 24 h initiated 12 h prior to surgery Extended prophylaxis may be given for up to 3 wk	Postoperative start: 2,500 units SC given 4-8 h after surgery then 5,000 international units SC q 24 h *or* Preoperative start (evening before surgery): 5,000 units SC 10–14 h before surgery then 5,000 units given 4–8 h after surgery then 5,000 units SC q 24 h *or* Preoperative start (day of surgery): 2,500 units SC within 2 h of surgery, then 2,500 units given 4–8 h after surgery then 5,000 units SC q 24 h	
Knee-replacement surgery (prophylaxis)	30 mg SC q 12 h initiated 12–24 h after surgery		
Abdominal surgery (prophylaxis)	40 mg SC q 24 h initiated 2 h prior to surgery	2,500 units SC q 24 h initiated 1–2 h prior to surgery Patients with malignancy: 5,000 units SC the evening prior surgery then 5,000 units SC q 24 h *or* 2,500 units SC 1–2 h prior to surgery then 2,500 units 12 h after surgery followed by 5,000 units SC q 24 h	
Acute medical illness (prophylaxis)	40 mg SC q 24 h	5,000 units SC q 24 h	
Deep vein thrombosis treatment (with or without pulmonary embolism)	1 mg/kg SC q 12 h *or* 1.5 mg/kg SC q 24 h		175 units/kg SC q 24 h
Venous thromboembolism treatment in patients with cancer		200 units/kg SC q 24 h for 30 days, followed by 150 units SC q 24 h (total daily dose should not exceed 18,000 units)	

osteoporosis-related fractures.[16] However, UFH has been used successfully in pregnant patients without evidence of osteoporosis.[32] Unfractionated heparin is not excreted in breast milk and is considered safe to use by women who are breastfeeding.[16]

Advances in tertiary care for pediatric patients have resulted in increasing numbers of children requiring antithrombotic therapy, and UFH is commonly used in this setting (see General Approach to the Treatment of Venous Thromboembolism below).[33]

LOW-MOLECULAR-WEIGHT HEPARIN

Produced by either chemical or enzymatic depolymerization (see Table 26–6), LMWHs are fragments of UFH.[5] They are heterogeneous mixtures of sulfated glycosaminoglycans with approximately one-third the molecular weight of UFH. Although all the LMWHs share similarities in their mechanisms of action with UFH, their molecular weight distributions vary, resulting in differences in their activity against factor Xa and thrombin, affinity for plasma proteins, propensity to release tissue factor pathway inhibitor, and duration of activity.[28] The mean molecular weight of the LMWHs is product specific. These agents have several advantages over UFH, including (a) predictable anticoagulation dose response, (b) improved subcutaneous bioavailability, (c) dose-independent clearance, (d) longer biologic half-life, (e) lower incidence of thrombocytopenia, and (f) a reduced need for routine laboratory monitoring.[5]

Currently, there are three LMWH products available in the United States. The usefulness of LMWHs has been extensively evaluated for a wide array of indications, including the treatment of acute coronary syndromes, DVT, and PE, as well as for the prevention of VTE in several high-risk populations. The FDA-approved indications and doses for the LMWHs are product specific (Table 26–10). The LMWHs have largely replaced UFH for the prevention and treatment of VTE in some hospitals. However, institutional resources and individual patient needs should determine their precise role in the management of VTE.

Pharmacology

The LMWHs prevent the growth and propagation of formed thrombi. Like UFH, the LMWHs enhance and accelerate the activity of antithrombin through binding to a specific pentasaccharide sequence. Fewer than one third of LMWH molecules contain the specific sequence necessary to interact with antithrombin.[5] The principal difference in the pharmacologic activity of the LMWHs and UFH is their relative inhibition of factor Xa and thrombin. Because of their smaller chain length, the LMWHs have limited activity against thrombin (see Fig. 26–5). Fewer than 50% of the LMWH molecules have the requisite chain length to simultaneously bind antithrombin and thrombin. For this reason, the LMWHs have proportionally greater antifactor Xa activity. The ratio of antifactor Xa-to-IIa activity varies between 4:1 and 2:1.[5] By comparison, UFH has an antifactor Xa-to-IIa activity ratio of 1:1. Like UFH, the LMWHs cause the endothelium to release tissue factor pathway inhibitor, which is believed to enhance the inhibition of factor Xa and to inactivate factor VIIa.[28]

Pharmacokinetics

Compared with UFH, the LMWHs have a more predictable anticoagulation response. The improved pharmacokinetic profile of LMWHs is the result of reduced binding to proteins and cells.[5] The bioavailability of LMWHs is about 90% when administered subcutaneously, whereas the absorption of UFH is relatively poor and erratic. The subcutaneous bioavailability of the available LMWH products differs only slightly. The peak anticoagulation effect is seen in 3 to 5 hours.[5]

The renal route is the predominant mode of elimination for the LMWHs. Consequently, their biologic half-life may be prolonged in patients with renal impairment. Longer heparin chains bind to macrophages and are rapidly degraded. Therefore, antifactor Xa activity, which is mediated by smaller heparin molecules, persists longer than antithrombin activity. The plasma half-life of the LMWH preparations is two to four times longer than UFH. The clearance of LMWHs is independent of dose.[5]

Dosing and Administration

The LMWHs are given in fixed or weight-based doses based on the product and indication (see Table 26–10). Doses should be based on actual body weight and studies in obese patients indicate that full weight-based doses do not lead to elevated LMWH concentrations when compared with normal subjects; consequently, capping of the dose is not recommended.[30] The dose for enoxaparin is expressed in milligrams, whereas dalteparin and tinzaparin are expressed in units of antifactor Xa activity. Although they can be given by continuous intravenous infusion, the LMWHs are generally given by subcutaneous injection in the abdominal area or the upper outer part of the thigh while the patient is in a supine position. The clinician or patient pinches a layer of skin between the thumb and forefinger, and then introduces the entire length of the needle into a skin fold at a 90° angle. Injection sites should be alternated between right and left sides. Following subcutaneous administration, the drug is absorbed slowly, resulting in sustained antithrombotic activity over several hours.

The dosing interval for the LMWHs is every 12 or 24 hours depending on the indication and product. Larger doses are given once daily and produce significantly higher peak plasma concentrations. Given that the elimination half-life of the LMWHs is prolonged in patients with severe renal impairment, high doses may lead to a significant accumulation in these patients.[5] The enoxaparin dose should be reduced and the dosing interval extended to once daily in patients with creatinine clearance <30 mL/min.[34] The pharmacokinetics of dalteparin and tinzaparin are less-well characterized in patients with renal insufficiency, but some studies suggest that there is a lower degree of accumulation with tinzaparin.[5] Data on the use of LMWH in patients with end-stage renal disease receiving hemodialysis is very limited, thus UFH is preferred for these patients.[5] Given that few published data are available regarding the use of LMWHs in the setting of renal insufficiency, some experts recommend measuring antifactor Xa activity if therapy is continued for more than a few days.[5]

For the prevention of VTE, the LMWHs have been studied in a variety of high-risk circumstances, including orthopedic surgery, abdominal surgery, acute spinal cord injury, neurosurgery, multiple trauma, and critical illness.[2] The effectiveness of the LMWHs has been extensively evaluated for the treatment of VTE in hospitalized patients and used in the outpatient management of DVT.[6] They are also a reasonable alternative to warfarin therapy in circumstances when a prothrombin time (PT)/international normalized ratio (INR) can not be routinely obtained.

Therapeutic Monitoring

Because the LMWHs achieve predictable anticoagulant response when given subcutaneously, routine laboratory monitoring is unnecessary to guide the dosing of these agents.[5] The PT, the ACT, and the aPTT are minimally affected by LMWHs.[28] Prior to initiation of LMWH, a baseline complete blood cell count with platelet count, and serum creatinine should be obtained. The complete blood cell count should be checked every 5 to 10 days during the first 2 weeks of LMWH therapy and every 2 to 4 weeks thereafter to monitor for occult bleeding.

Although several methods to monitor LMWHs have been explored, measurement of antifactor Xa activity has been the most widely used method in clinical practice. Routine antifactor Xa activity measurement is unnecessary in patients whose condition is stable and uncomplicated.[5] Although very limited data support the use of laboratory monitoring to guide LMWH therapy, measuring antifactor Xa activity may be helpful in patients who have significant renal impairment (e.g., creatinine clearance <30 mL/min), weigh less than 50 kg, are morbidly obese, or require prolonged therapy (e.g., longer than 14 days). Periodic antifactor Xa activity monitoring may also be useful in women treated with a LMWH during pregnancy because of changing pharmacokinetic variables (e.g., volume of distribution and renal function).[5] Patients who are at very high risk of bleeding or thrombotic recurrence may also benefit from antifactor Xa monitoring to avoid periods of over-or underanticoagulation. Because newborns and pediatric patients have unpredictable pharmacokinetic profiles, they may require monitoring to ensure adequate therapy.[33]

When anti-factor Xa activity is used to monitor LMWH therapy, the sample should be drawn after steady state has been achieved (after the second or third dose) and approximately 4 hours after the subcutaneous injection, during the peak period of antifactor Xa activity.[28] A calibrated LMWH heparin should be used to establish the standard curve for the assay. The therapeutic range for antifactor Xa activity is not well defined and not been clearly correlated with efficacy or the risk of bleeding.[5] For the treatment of VTE, an acceptable target range for the peak level is 0.6 to 1.0 units/mL with twice daily enoxaparin or nadroparin dosing. For once daily dosing likely peak targets are >1 units/mL for enoxaparin, 0.85 units/mL for tinzaparin, 1.3 units/mL for nadroparin, and 1.05 units/mL for dalteparin.[5] For the prevention of VTE an acceptable target range for the peak level is 0.2 to 0.4 units/mL.

Adverse Effects

As with UFH, bleeding is the most common adverse effect of the LMWHs.[3] Although not consistently demonstrated in clinical trials, the frequency of major bleeding is purported to be less with the LMWHs than with UFH.[3] This difference may be partly a result of their reduced effects on platelet function, endothelial cells, and microvascular permeability. The incidence of major bleeding reported in clinical trials is less than 3% and varies among the LMWH preparations, their indication for use, patient population, and dose administered. Minor bleeding, particularly at the site of injection, occurs frequently with LMWH use. Epidural and spinal hematoma resulting in long-term or permanent paralysis have been reported with the use of LMWH during spinal and epidural anesthesia or spinal puncture.[34] The risk of these events is higher with the use of indwelling epidural catheters and concomitant use of drugs that affect hemostasis. Patients should be frequently monitored for signs and symptoms of neurological impairment. If neurological compromise is noted, urgent treatment is necessary.[34]

Although there is no proven method for reversing LMWH, if major bleeding does occur in a patient receiving an LMWH, it is recommended that IV protamine sulfate be administered.[5] However, because of its limited binding to the shorter LMWH chains, protamine sulfate cannot completely neutralize the anticoagulant effects of LMWH. When given in equimolar concentrations, protamine

sulfate neutralizes an estimated 60% to 75% of the antithrombotic activity of LMWH. The recommended dose of protamine sulfate is 1 mg/1 mg of enoxaparin or 1 mg/100 anti-factor Xa units of dalteparin or tinzaparin administered in the previous 8 hours. A second protamine sulfate dose of 0.5 mg/100 anti-factor Xa can be given if bleeding continues. Smaller doses of protamine sulfate can be used if the LMWH dose was given in the previous 8 to 12 hours. The use of protamine sulfate is not recommended if the LMWH was administered more than 12 hours earlier.[5]

Although thrombocytopenia can occur with the use of a LMWH, the incidence of HIT is substantially lower than that observed with the use of UFH.[5,31] The explanation may lie in the reduced propensity of the LMWHs to bind to platelets and PF-4.[5] Because the LMWHs exhibit nearly 100% cross-reactivity with heparin antibodies in vitro, the LMWHs should be avoided in patients with an established diagnosis or history of HIT.[31] Platelet counts should be periodically monitored in all patients who are receiving LMWH, and thrombocytopenia of any degree should be promptly evaluated. The risk of osteoporosis appears to be lower with the LMWHs than with UFH, but both agents have the potential to produce osteopenia.[5]

Use in Special Populations

There is growing experience with the use of LMWHs during pregnancy.[16] The LMWHs do not cross the placenta. According to the results of a few large case series, the LMWH appear to be relatively safe to use during pregnancy and are an attractive alternative to UFH when long-term anticoagulation therapy is required. Furthermore, the LMWHs may have less effect on bone formation.[16] Dalteparin, enoxaparin, and tinzaparin are classified as FDA pregnancy category B.

The LMWHs are becoming the preferred agents in pediatric populations despite the fact that the safety and effectiveness of the LMWHs to treat VTE in children and infants has not been extensively studied. The reduced need for routine monitoring associated with LMWH is especially attractive as many pediatric patients have limited venous access.[33] Weight-based LMWH doses provide a less-predictable anticoagulant response in children compared to adults. For enoxaparin, suggested therapeutic doses are 1.5 mg/kg every 12 hours for infants <2 months old and 1.0 mg/kg every 12 hours for those >2 months old. The suggested dose for dalteparin is 86 to 172 units/kg every 24 hours, keeping in mind that neonates appear to require higher doses/kg than older children or adults.[33] Until more data are available, it is prudent to periodically monitor anti-factor Xa activity in these special populations during long-term use.[33]

FONDAPARINUX

Fondaparinux, also known as pentasaccharide, is a synthetic molecule consisting of the five critical saccharide units that bind specifically, but reversibly, to antithrombin (see Fig. 26–5).[5] Fondaparinux is the first in a class of anticoagulants that selectively inhibits factor Xa activity.[35]

Pharmacology

Similar to UFH and the LMWHs, fondaparinux prevents thrombus generation and clot formation by indirectly inhibiting factor Xa activity through its interaction with antithrombin. When fondaparinux binds to antithrombin it causes a permanent conformational change in antithrombin's active site and catalyzes antifactor Xa activity by about 300-fold.[36] Fondaparinux is not destroyed during this process and is released to bind many other antithrombin molecules.[5] Unlike UFH and LMWH, fondaparinux has no direct effect on thrombin activity at therapeutic plasma concentrations.[5] Selective inhibition of factor Xa may provide more efficient control over fibrin generation while preserving thrombin's regulatory functions in the control of hemostasis. Fondaparinux has no known effect on platelet function.[36]

Pharmacokinetics

Fondaparinux is rapidly and completely absorbed following subcutaneous administration (absolute bioavailability 100%). Peak plasma concentrations are achieved in approximately 2 hours after a single dose and 3 hours with repeated once-daily dosing. It is distributed primarily in blood. At therapeutic concentrations, fondaparinux is highly and specifically bound to antithrombin. It does not bind to red blood cells or other plasma proteins including albumin, glycoprotein, platelets, or PF4.[5] Fondaparinux is primarily eliminated unchanged in the urine. It is contraindicated in patients with severe renal function impairment (creatinine clearance <30 mL/min). The terminal elimination half-life is 17 to 21 hours and is independent of the patient's age or sex.[5] The anticoagulant effect of fondaparinux persists for 2 to 4 days following discontinuation of the drug in patients with normal renal function. Fondaparinux has no known pharmacokinetic drug interactions. However, concurrent use with other drugs with antithrombotic activity increases the risk of hemorrhage.[37]

Dose and Administration

Fondaparinux is FDA-approved for the prevention of VTE following orthopedic (hip fracture, hip replacement, and knee replacement) or abdominal surgery and for the treatment of DVT and PE (in conjunction with warfarin).[37] In the setting of VTE prevention, the dose of fondaparinux is 2.5 mg injected subcutaneously once daily starting 6 to 8 hours following surgery providing hemostasis has been established. It is important to avoid initiating fondaparinux too soon because there is a significant relationship between the timing of the first dose and the risk of major bleeding complications. Patients who weigh less than 50 kg should not be given fondaparinux for VTE prophylaxis. The usual duration of therapy is 5 to 9 days, but may be given as extended prophylaxis following hospital discharge for up to 21 days.[37] For the treatment of DVT or PE, the dose of fondaparinux is 7.5 mg given subcutaneously once daily. Patients who weight more than 100 kg should be given 10 mg once daily and those who weigh less than 50 kg should receive only 5 mg daily.[37]

Similar to the LMWHs, fondaparinux is administered into the fatty tissue of the abdominal wall. Patients should be instructed to pinch a fold of skin at the injection site and hold it throughout the injection. The needle should be inserted at a 90° angle. Injection sites should be alternated from side to side.[37]

CLINICAL CONTROVERSY

The ACCP Clinical Practice Guidelines recommend against the use of aspirin as the primary method of VTE prophylaxis. However, the American Academy of Orthopedic Surgeons continues to advocate for the use of aspirin 325 mg daily for the prevention of PE following hip and knee replacement surgery. While antiplatelet drugs clearly reduce the risk of coronary artery and cerebrovascular events in patients with arterial disease, aspirin produces a very modest reduction in VTE following orthopedic surgeries of the lower extremities. The relative contribution of platelets in the pathogenesis of venous thrombosis compared with that of arterial thrombosis can explain the reason for this difference.

Therapeutic Monitoring

A complete blood cell count should be measured at baseline and monitored periodically to detect the possibility of occult bleeding.[37] Baseline kidney function should be determined and monitored closely in patients at risk of developing renal failure. Fondaparinux should be discontinued if the creatinine clearance drops below 30 mL/min. Signs and symptoms of bleeding should be monitored daily, particularly in patients with a baseline creatinine clearance between 30 and 50 mL/min. If neuraxial anesthesia has been used, patients should be closely monitored for signs and symptoms of neurologic impairment.

Fondaparinux does not alter coagulation tests such as the aPTT and PT. The role of antifactor Xa monitoring during fondaparinux is not well defined. Patients receiving fondaparinux therapy do not require routine coagulation testing. The anticoagulant activity can be measured with using anti-Xa assays provided fondaparinux is used as a reference standard.[5]

Adverse Effects

The primary adverse effect associated with fondaparinux therapy is bleeding.[37] The rate of major bleeding in the VTE prophylaxis trials was approximately 2% to 3%. Because the risk of major bleeding appears to be related to weight, in patients who weigh less than 50 kg, fondaparinux is contraindicated for VTE prophylaxis and the treatment dose is only 5 mg every 24 hours. Similar to UFH and the LMWHs, fondaparinux should be used with extreme caution in patients with neuraxial anesthesia or following a spinal puncture because of the risk for spinal or epidural hematoma formation. Some case reports have documented successful treatment of HIT with fondaparinux, while others have implicated fondaparinux as a cause of HIT.[38] A specific antidote to reverse the antithrombotic activity of fondaparinux is not currently available, if uncontrollable bleeding occurs during fondaparinux therapy, factor VIIa may be effective.[5]

Use in Special Populations

Fondaparinux has been used safely in elderly patients but the risk of major bleeding increases with age.[37] This is an important consideration because many patients who undergo orthopedic surgery are elderly. Elderly patients are also more likely to have decreased renal function and careful assessment of renal status should be conducted prior to initiating therapy.

Fondaparinux is a pregnancy category B drug.[37] However, there is very limited information regarding fondaparinux use during pregnancy. The drug is excreted in the milk of lactating rats, but excretion in human milk is unknown. Until more data becomes available, UFH and LMWH should remain the agents of choice during pregnancy. Fondaparinux use in pediatric populations has not been studied. Because the dose of fondaparinux is 10 mg for all patients >100 kg, some prefer fondaparinux for VTE treatment in obese patients.

IDRAPARINUX

Idraparinux is an experimental analog of fondaparinux that has very long duration of effect (see Table 26–6) and was developed to be administered once weekly by subcutaneous injection.[35] Idraparinux has shown similar efficacy and safety as warfarin in the treatment of DVT but was less effective than warfarin in patients with PE.[6] A drug that increases bleeding risk with duration of effect persisting for a week is concerning. A novel biotinylated formulation of idraparinux (SSR 126517) has been developed that can be rapidly reversed with injection of avidin an egg white protein.[35] Avidin binds biotin with high affinity to form a stable complex that is renally cleared within minutes terminating the anticoagulant effect of SSR 126517.[39] Further development of idraparinux has been halted with focus turning to SSR 126517. Whether biotinylation of idraparinux will improve results in the treatment of VTE remains to be defined.[39]

EMERGING ANTI-XA INHIBITORS

The introduction of LMWH and fondaparinux transformed the initial treatment of VTE from a purely inpatient endeavor to one where the majority of patients can be treated as outpatients. However, the need for daily subcutaneous injections is a significant barrier for some patients.[39] Warfarin therapy poses even greater challenges as discussed previously and the required monitoring is labor intensive and stressful for patients and anticoagulation providers.[40] These shortcomings in available anticoagulants have driven the search for replacements with rapid onset of effect that can be administered orally without the need for anticoagulant monitoring. Two such agents that target factor Xa, rivaroxaban and apixaban are in advanced stages of clinical development. Rivaroxaban has been approved in Europe and Canada for prevention of VTE following orthopedic surgery.[40]

Pharmacology and Pharmacokinetics

Rivaroxaban and apixaban are potent and selective inhibitors of factor Xa that do not require antithrombin to exert their anticoagulant effect.[39] Both drugs have good oral bioavailability (80% and 50% for rivaroxaban and abixaban, respectively) and reach peak plasma concentrations in about 3 hours.[39] The terminal half-life of rivaroxaban is 5 to 9 hours and 9 to 14 hours for abixaban.[39] Both drugs are excreted in the urine and feces and are metabolized by CYP 3A4 (among others) and CYP-independent mechanisms.[39] Inhibitors of CYP3A4 and P-glycoprotein may increase plasma concentrations of either drug.[40]

Monitoring

Rivaroxaban and abixaban prolong the PT and the aPTT. For rivaroxaban, the effect on PT and aPTT is short-lived and only appreciable at peak concentrations. Apixiban's effect on PT and aPTT is minimal at therapeutic concentrations. Both drugs can be monitored using factor Xa inhibition assay; however, clinical trials have demonstrated that routine coagulation monitoring is unnecessary for either.[39]

Opportunities and Limitations

Rivaroxaban and apixaban represent a potential advancement in the prevention and treatment of VTE. The rapid onset of effect of these new agents could eliminate the need for injectable anticoagulants in the initial management of VTE. Fixed dosing without the need for routine coagulation monitoring and less drug interaction potential would also offer advantages over warfarin for long-term VTE management.[39]

The lack of a safe, rapidly acting antidote for either of these agents may complicate the management of patients who develop bleeding during treatment.[39] While the lack of routine coagulation monitoring is generally regarded as beneficial, there are instances when monitoring is helpful. Examples include patients with renal or hepatic impairment or in those taking drugs that could affect the metabolism of rivaroxaban or abixaban. Without knowledge of the degree of coagulation inhibition in these circumstances, it will be difficult to know if dose adjustments are necessary to prevent the risk of adverse events.[39] The routine coagulation monitoring associated with warfarin provides a method to assess compliance with therapy. Compliance with new anticoagulants may be more challenging to assess and will require careful patient supervision.[39] The cost of rivaroxaban and abixaban may limit use, particularly if no

TABLE 26-11 Pharmacologic and Clinical Properties of Direct Thrombin Inhibitors

	Lepirudin	Desirudin	Bivalirudin	Argatroban	Dabigatran[a]
Route of administration	IV or SC	IV or SC	IV	IV	PO
Indication	Treatment of thrombosis in patients with HIT	DVT prevention after THA (not available in the U.S.)	Patients with UA undergoing PTCA; PCI with provisional use of GPI Patients with or at risk for HIT undergoing PCI	Treatment of thrombosis in patients with HIT; patients at risk for HIT undergoing PCI	Investigational for VTE prevention and treatment, and stroke prevention in AF
Binding to thrombin	Irreversible catalytic site and exosite-1	Irreversible catalytic site and exosite-1	Partially Reversible catalytic site and exosite-1	Reversible catalytic site	Reversible catalytic site
Monitoring	aPTT (IV) S_{cr}/Cl_{cr}	aPTT (IV) S_{cr}/Cl_{cr}	aPTT/ACT S_{cr}/Cl_{cr}	aPTT/ACT Liver function	S_{cr}/Cl_{cr} Effect on liver function unclear at this time[b]
Clearance	Renal	Renal	Enzymatic (80)% and Renal (20%)	Hepatic	Renal
Antibody development	Antihirudin antibodies in up to 60% of patients	Possible; lower incidence than with lepirudin	May cross-react with antihirudin antibodies	No	Unknown
Effect on INR	Slight increase	Slight increase	Slight increase	Increase	Unpredictable and variable

ACT, activated clotting time; AF, atrial fibrillation; aPTT, activated partial thromboplastin time; Cl_{cr}, creatinine clearance; DVT, deep vein thrombosis; HIT, heparin induced thrombocytopenia; INR, international normalized ratio; IV, intravenous; PCI, percutaneous coronary intervention; PO, oral; SC, subcutaneous; S_{cr}, serum creatinine; THA, total hip arthroplasty; VTE, venous thromboembolism.

[b] Routine monitoring of anticoagulant effect may not be necessary.

From Nutescu et al.[42]

efficacy and/or safety advantage can be demonstrated in comparison to existing anticoagulants. As many patients with VTE will require indefinite anticoagulation therapy, the long-term safety of these new agents will need to be established.[40] Until providers become comfortable with new anticoagulants and the cost differential with existing agents narrows, these drugs may initially be second-line choices for patients who cannot be adequately controlled on warfarin or for those in whom routine coagulation testing cannot be readily performed (e.g., geographic inaccessibility, poor venous access).[39]

DIRECT THROMBIN INHIBITORS

In recent years, research has focused on the development of direct thrombin inhibitors (DTIs) that may offer benefits over traditional agents in the treatment and prevention of various thrombotic disorders. The DTIs have been studied for many indications such as HIT, prophylaxis and treatment of VTE, acute coronary syndromes with and without percutaneous transluminal coronary angioplasty, and nonvalvular atrial fibrillation. Currently four parenteral agents—lepirudin, desirudin, bivalirudin, and argatroban—are approved for use in the United States, and several oral compounds are in various phases of clinical development (Table 26–11).[41,42]

Pharmacology and Pharmacokinetics

The direct thrombin inhibitors, as their name implies, directly interact with the thrombin molecule (see Fig. 26–6). The agents in this class differ in terms of their molecular weight, chemical structure, and binding to the thrombin molecule. Unlike UFH, LMWH, and fondaparinux, DTIs do not require a cofactor (antithrombin) to exert their antithrombotic activity. They are capable of inhibiting both circulating and clot-bound thrombin, a potential advantage over UFH and LMWH. Furthermore, DTIs do not induce immune mediated thrombocytopenia and are widely used for the treatment of HIT.[41,42]

Hirudin, the prototype of this class, is a 65-amino-acid polypeptide that was originally isolated from the salivary secretions of the medicinal leech (*Hirudo medicinalis*). Although not commercially available, the discovery of hirudin led to the development of derivatives such as lepirudin and desirudin via recombinant DNA technology. The hirudins (lepirudin, desirudin, and bivalirudin) form a stoichiometric and very slowly reversible complex by binding to both the active site and exosite-1 of the thrombin molecule (see Fig. 26–6). Because of this bivalent bond, hirudins are considered the most potent inhibitors of thrombin.[41,42]

Lepirudin, a recombinant analogue of hirudin, is a 65-amino acid polypeptide that is administered parenterally, either by continuous IV infusion or subcutaneous injection.[43] It is indicated for anticoagulation in patients with HIT and associated thrombosis to prevent further thromboembolic complications. Research is also being conducted on the use of lepirudin for other indications, such as acute coronary syndromes and VTE. Because of the strong, almost irreversible bond between lepirudin and thrombin, lepirudin is associated with bleeding complications.[43] The primary route of elimination for lepirudin is through renal excretion, and systemic clearance is directly proportional to the glomerular filtration rate. Lepirudin has a terminal half-life of 1.3 hours in young healthy volunteers. In patients with marked renal insufficiency (ClCr <15 mL/min) and on hemodialysis, elimination half-lives are prolonged up to 2 days.[41,42] Thus, dose adjustment is required in the setting of impaired renal function, a potential disadvantage of this agent (Table 26–12). Many patients develop antibodies to lepirudin. Up to 60% of patients treated with lepirudin for 10 days or more will develop antibodies. This may increase the anticoagulant effect of lepirudin, possibly as a result of delayed renal elimination of active lepirudin–antihirudin complexes. Consequently, strict monitoring of aPTT is necessary during prolonged therapy.[41,42] Because fatal anaphylaxis has been reported in patients who developed antibodies, patients should not be treated with lepirudin more than once.[44]

Desirudin, also a recombinant hirudin analogue, is administered by subcutaneous injection and approved by the FDA in 2003 for the prevention of venous thrombosis in patients undergoing elective hip surgery. Although approved for use, the agent is not currently commercially available in the United States. Studies are evaluating the use of subcutaneous desirudin for the treatment of HIT. For acute myocardial infarction and unstable angina, desirudin has
